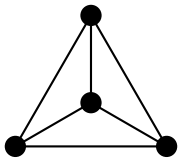
Void

An Eliminative Ontology of Distinction

Johannes Michael Wielsch



Machine-verified in Agda

For Lara, Lia, and Lukas.

May you always question, and may the questions be beautiful.

Abstract

Begin with nothing. No axioms, no substances, no space, no time—the unmarked state before any distinction has been drawn.

Now ask: what survives? Not what can be built, but what cannot be destroyed. Apply the filter of self-consistency—mechanically, without exception—and trace what remains when every structure that contradicts itself has been annihilated. The method is elimination: twenty-five thousand lines of machine-verified destruction, not construction, carried out in Agda under the flags --safe and --without-K, with no postulates and no external axioms.

The answer is not a model. It is a verdict—and a specific one. A single structure survives the filtration: the complete graph K_4, four vertices bound by six edges. Not "some graph exists" but "exactly one graph survives, and its invariant record is unique." The gap between starting with nothing and arriving at a named, rigid object is the central surprise of the derivation.

The survivor is austere but fertile. Its combinatorial invariants—vertex count, edge topology, spectral decomposition, Euler characteristic—are necessities, not parameters. From these invariants, the number systems themselves are forced: the naturals by counting, the integers by orientation, the rationals by spectral ratio, the reals by Cauchy closure. No number system is imported. Every algebraic law is a theorem.

Two independent routes reach the same root. The eliminative chain derives distinction as the necessary starting point of any consistent formal system. The measurement kernel derives it from the opposite end: any apparatus that separates yes from no already presupposes the distinction it claims to discover. The two routes share no lemma and no definition; their convergence is structural.

The chain closes. The book's final theorem proves that any admissible invariant record already presupposes a distinction—the first act the void performs upon itself. The starting point cannot be dropped, because it was never assumed. It is what the void already is, the moment it is examined.

A derivation so compressed touches many disciplines at once—logic, combinatorics, group theory, spectral analysis—and every one of them was built by someone else. The debts are large because the chain is long.

Inheritance

None of the ideas in this work are new. The derivation is a single thread; what follows names the hands that spun it.

The starting point—that a distinction, not a thing, is the irreducible atom of form—belongs to George Spencer-Brown. The conviction that this is not metaphor but structure—that form reduces to yes-or-no at every point—is the wager this formalization accepts.

That such a claim can be made rigorous at all is owed to the constructivists. Brouwer insisted that existence demands a witness. Heyting gave that demand algebraic form. Curry and Howard revealed that proofs and programs are the same act. Per Martin-Löf forged these insights into a type theory strong enough to carry mathematics, and Voevodsky showed what must be given up—axiom K, uniqueness of identity proofs—if homotopy is to be taken seriously. Every line of this work executes inside those constraints.

The combinatorial backbone has older roots. Euler first counted vertices, edges, and faces as a single invariant. Cayley classified graphs by their symmetries. Birkhoff established when a representation is canonical—when structure admits exactly one normal form. These are the tools that force K_4, and only K_4, out of the filtration.

That the spectral analysis of the survivor is determined by these tools is owed to the tradition built by Fourier, Laplace, and Hilbert. In this work, the Laplacian of K_4 yields a spectrum—$\{0, 4, 4, 4\}$—that was not chosen but inherited.

What determines which quantities are invariant is the automorphism group, and its theory has its own lineage. Galois revealed that solvability is a property of the group, not the equation. Here, the automorphism group $\mathrm{Aut}(K_4) \cong S_4$ is the arbiter: only quantities invariant under it factor through the canonical base.

The categorical perspective—that structure is characterized not by what it *is* but by the maps it *admits*—descends from Lawvere and the tradition of Tarski, where fixpoints are not found but forced by the architecture of the logic itself.

What this work contributes is not a new insight. It is a tool applied: the Agda type checker, which enforces logical consistency without exception, turned loose on the question these people raised from different directions. If the result has any value, it is because the filter is trustworthy—not because the author is clever.

Chapter 1

Introduction

Three Questions, One Filter

The void is the unmarked state. This observation—that a system capable of examining itself already distinguishes examination from non-examination—has appeared independently in logic and in the foundations of mathematics. It has been stated. It has not been derived from nothing, mechanically, without axioms. This book derives it.

Two disciplines have arrived at this boundary independently.

Mathematics asks: which structures are consistent? Logic asks: which statements can be decided at all?

Different languages, different traditions—and yet, when pushed far enough, both converge on the same mechanism: an internal filter that neither chose. Mathematics eliminates structures that contradict themselves. Logic eliminates propositions that cannot be assigned a truth value without inconsistency.

What cannot stand under its own requirements, falls. The stages differ. The verdict is identical.

If the filter is the same everywhere, could the survivor also be the same?

Elimination as Method

The standard approach in formal work is constructive: posit axioms, define structures, prove theorems, build upward. The direction is from assumption to consequence.

This work begins from the opposite end—the void.

Nothing is assumed. Nothing is postulated. The starting point is not a structure but the absence of structure, and then a relentless filter is applied. At every stage, the question is the same: which structures survive their own consistency requirements? Those that do not are annihilated. Those that do, persist—not by choice, but because elimination could not reach them.

This is not a new idea. It is how logic has always worked. But the full consequences of applying this filter mechanically, from the ground up, without exception, have not been traced before. This book traces them.

The filter produces something disconcerting: the more rigorously nothing is assumed, the more specific the forced conclusion. This is the inverse of what ordinary formal work suggests—fewer axioms should give more models, not fewer. What the derivation shows is that the absolute minimum forces the maximum specificity. One graph. One record. One arithmetic. One loop.

The Tool: Agda as Executioner

A filter is only as trustworthy as its enforcement. Human reasoning is fallible: it overlooks edge cases, confuses sufficiency with necessity, and mistakes intuition for proof. This is why every step in this work is formalized and verified in Agda, a dependently typed proof assistant.

Agda does not care about elegance or plausibility. It checks one thing: does this term have the type it claims to have? If yes, the step stands. If no, it is rejected. There is no override, no escape hatch.

The compiler flags used in this work—`--safe` and `--without-K`—further restrict the environment. No external axioms can be assumed. No postulates can be introduced. No appeal to the uniqueness of identity proofs is permitted. The system is locked into the narrowest possible corridor of logical consistency, and then forced to walk.

What Happens Here

The global line of force has a single irreversible spine:

$$D_0 \longrightarrow \text{minimal logical infrastructure} \longrightarrow \text{classification} \longrightarrow \text{drift and reachability}$$
$$\longrightarrow \text{presentation and fixpoint} \longrightarrow K_4 \longrightarrow \text{arithmetic and spectral invariants} \longrightarrow \text{invariant record} \longrightarrow D_0.$$

The spine does not branch—and it does not dead-end. The book's final theorem closes the loop: any admissible invariant record already presupposes D_0. The chain is not an open arrow; it is a closed constraint.

The Elimination Protocol

The eliminative chain has a compact ledger. At every step below, the column on the right names the alternatives that were tested and destroyed. K_4 is what stands after every row has been executed. Nothing in this list was chosen; everything was forced by the failure of its rivals.

#	Survivor	Why it survives	What was eliminated
1	Distinction (D_0)	The bare act of separating ℓ from r. Any formal system that cannot distinguish true from false is vacuous. Uniquely among all rows: denying D_0 is itself an act of distinguishing, so its negation is self-refuting.	Vacuous carriers, carriers without boundary witnesses, carriers where $\ell = r$.
2	Two-class coverage	Every element of the carrier equals ℓ or r. No unclassified residue is possible.	Carriers with hidden elements, partial classifications, carriers with > 2 equivalence classes.
3	Four endomorphisms	Coverage forces $\lvert\mathrm{End}(S)\rvert = 2 \times 2 = 4$. Each case is mutually distinct.	K_1 (1 vertex — cannot host 4 distinct maps), K_2 (2 vertices — collapses constant maps), K_3 (3 vertices — one case always orphaned).
4	Drift acyclicity	Applying classification to classification produces a level tower. The reachability relation on that tower is well-founded.	Cyclic level structures, infinite descending chains, non-well-founded hierarchies.
5	Presentation fixpoint	Every reachability witness reduces to a canonical finite form. The observable that measures proofs factors through a unique base.	Non-canonical representations, observables that depend on proof-internal choices, redundant witnesses.
6	K_4	The complete graph on four vertices is the unique fixpoint of the filter. No proper subgraph survives all five constraints above.	Every proper subgraph of K_4, every supergraph, every non-complete topology on four vertices.
7	Derived arithmetic	K_4 forces counting (naturals), orientation (integers), spectral ratios (rationals), limit closure (reals).	Number systems not grounded in K_4 structure, algebraic laws that contradict the spectral data.
8	Invariant record	The combinatorial invariants of K_4 ($V = 4$, $E = 6$, $d = 3$, $\chi = 2$, $\mathrm{Spec} = \{0, 4, 4, 4\}$) yield $\mathcal{C} = 137$ by evaluation. No free parameter.	Any alternative assignment that would require a different graph or a tunable parameter.

No branch exists. Uniqueness is not asserted; it is proved twice over: once for the graph (Part IV establishes K_4 as the sole fixpoint), and once for the invariant record (Chapter 45 proves that any two admissible records must agree on all fields).

This book proceeds in six parts. The first four derive K_4 through elimination. The fifth builds the arithmetic its structure makes necessary. The sixth assembles the invariant record its combinatorial data determine.

Part I (Foundation) establishes the minimal infrastructure that any consistent formal sys-

tem must carry: equality, pairing, negation, decidability, and the natural numbers. None is introduced by fiat. Each is the unique survivor when the alternative is tested for internal consistency and fails. The eliminative discipline begins here: even the infrastructure is not imported but forced.

Part II (Drift and Reachability) discovers what happens when classification is applied to classification itself. Each level of the type hierarchy is forced by the unclassified residue of the level below it. The tower that emerges has a structure rigid enough to determine its own height—the first sign that the survivor will be specific, not generic.

Part III (Heteromorphisms and Presentation) extends the classification to maps between two distinct carriers—not just within one. The same four cases survive. The presentation theorems reduce every reachability fact to a unique canonical witness—the uniqueness on which the singleton invariant record of Part VI will later rest.

Part IV (Observables and Fixpoint) identifies which quantities can be measured on proofs without depending on proof-choice. The answer is a fixpoint: every admissible observable factors through a unique base. The K_4 graph—four vertices, six edges, complete—is the unique structure that survives all constraints. The gap between nothing and this named, rigid object is now fully exposed.

Part V (Derived Arithmetic) builds the number systems that K_4's structure demands. Naturals arise from counting, integers from orientation, rationals from spectral ratios, reals from Cauchy closure. Every algebraic law is a theorem, not a postulate. No number system is imported. This is the methodological extreme of the derivation: the arithmetic used to evaluate the survivor is itself a consequence of the survivor.

Part VI (Derived Constants of K_4) assembles the invariants into a verified computation record, proves that record to be a singleton, establishes the measurement kernel as an independent route to the starting point, and closes the loop: any admissible invariant record already presupposes the distinction from which the chain began.

Each chapter slows down at a different point in the chain to verify that no weaker alternative survives. Every claim is machine-checkable: the source of this work is a literate Agda file where prose and code are one and the same document.

Why This Is Not Numerology

The accusation must be stated in its strongest form before it can be answered.

> *"You built a construction, and at the end 137 happens to fall out. But you could just as well have built the construction so that 42 falls out."*

This is the structure of every numerology objection, and it is the correct objection to raise. The question is whether it applies here. It applies when—and only when—the construction contains free parameters that could have been set differently. The answer depends on exactly one thing: *at which steps did the author have a choice?*

The elimination protocol above (§1) lists every step. The challenge is concrete: identify the step at which a genuine alternative existed—an alternative that the type checker would also accept—and that would produce a different graph, a different invariant, a different number.

The protocol has eight steps. At each step, the alternatives were tested and eliminated:

1. **Distinction.** The only alternative to "there is a distinction" is "there is not." The latter is vacuous—it produces no carrier, no types, no terms. This is not a choice; it is the decision to do formal work at all.

2. **Two-class coverage.** The alternative—a carrier with elements outside $\{\ell, r\}$—is contradicted by the coverage proof. The type checker enforces this.

3. **Four endomorphisms.** The count $2 \times 2 = 4$ is arithmetic forced by the carrier size. The claim that five or three endomorphisms could survive is refuted by exhaustive case analysis in the code.

4. K_4 **over any smaller graph.** K_3 fails because four mutually distinct vertices cannot close on three nodes. K_2 and K_1 fail earlier. The proofs are in Chapter 4.

5. **Drift and reachability.** The level tower is forced by applying classification to itself. Acyclicity is a theorem, not a design choice.

6. **Presentation fixpoint.** The collapse of observables to a unique canonical form is proven. The alternative—multiple incompatible canonical forms—would violate the uniqueness of the factoring proven in Part IV.

7. **Arithmetic.** Integers, rationals, and reals are derived from K_4 structure. The axioms of each number system are theorems, not postulates.

8. $\mathcal{C} = 137$**.** The formula $V^d \cdot \chi + d^2$ is the evaluation of K_4's combinatorial invariants. The values $V = 4$, $d = 3$, $\chi = 2$ are determined. The computation is $4^3 \cdot 2 + 3^2 = 128 + 9 = 137$. There is nothing to tune. The formal proof that this is the *unique* admissible degree-≤ 3 expression reaching a prime value is given by exhaustive classification in §28.

Numerology, by contrast, has a signature: the construction is chosen *after* the target is known, and the degrees of freedom are large enough that hitting the target is unsurprising. The test is simple. If the construction could equally well produce 42, or 139, or 11, by adjusting a parameter, then the result is numerological. If the construction is rigid—if the type checker would reject any modification of the intermediate steps—then the result is structural.

The claim here is narrower and harder: *the construction that produces 137 contains no adjustable parameter, and every step is machine-verified.* The machine-checked proof that $V^d \cdot \chi + d^2$ is the unique admissible survivor in the bounded evaluation sector appears in §28.

Two Paths, One Verdict

A companion volume, *Form*, derives K_4 by the opposite method: not elimination but construction. Starting from the mark D_0 as a single inhabited type, *Form* builds upward—witness, cut, Bool, natural numbers, integers, rationals, reals—until the complete graph appears as the unique structure the genesis sequence forces.

The two proof chains are independent. They share no derivation chain, no intermediate definitions, no common code. *Void* begins with abstract type-theoretic infrastructure—propositional equality, universe lifting, contractibility, distinct-pair classification—and then filters. *Form* begins with concrete inhabited types—D_0, D_1, D_2—and then constructs. The Agda modules do not import from each other.

The divergence extends deeper than subject matter: it reaches the proof machinery itself. The eliminative method asks, at every branching point, "can this alternative be ruled out?" That question is inherently propositional—it demands a witness of type Dec $(x \equiv y)$, a proof term that the type-checker must carry and reduce. As propositional chains grow, Agda's definitional reduction engine is forced to unfold long multiplication and Laplacian entries; the opaque keyword becomes necessary to keep the checker's memory bounded. None of this is a design decision—it is the cost of elimination.

The constructive method asks a different question: "what does this compute to?" That question is inherently computational—it demands a function of type $X \to X \to$ Bool, a decision procedure that pattern-matches to true or false and then forgets why. The reduction chains are shorter because the result is a bit, not a proof tree. Integer equality is checked by setoid comparison ($\simeq_{\mathbb{Z}}$), not by propositional unfolding. No opaque blocks are needed because the computational load never accumulates.

The method forces the machinery. An eliminative proof cannot use Bool decisions without losing the proof terms it needs for later elimination. A constructive proof cannot use propositional witnesses without carrying reduction weight it never discharges. Each path is locked into its own technology—not by preference, but by the logical grammar of its central verb.

This independence is not an accident. It is a consequence of the claim itself. If K_4 is truly the unique fixpoint of self-consistency, then it must be reachable from any direction. A result that can only be reached by one proof strategy is a result that depends on that strategy. A result that survives both elimination and construction depends on neither—it depends on the structure alone.

The two volumes converge on the same invariants: $(V, E, d, \chi, \kappa) = (4, 6, 3, 2, 8)$, the same Laplacian spectrum $\{0, 4, 4, 4\}$, the same derived constants, the same closed loop from D_0 back to D_0. That two independent formal developments, verified by the same compiler under the same flags, arrive at the same terminus is itself evidence—not proof, but evidence—that what they find is not an artifact of how they looked.

The reader who has access to both volumes may verify this convergence directly. The reader who has only this one loses nothing: the eliminative derivation is self-contained.

What This Book Does Not Contain

This volume contains no physics. No particle is named. No gauge group is invoked. No coupling constant is fitted. No unit of measurement—metre, second, kilogram, electronvolt—appears anywhere in the formal development. The number 137 is a theorem of K_4 combinatorics, not an approximation to an experimentally measured quantity. The loop numerator 11 is a survivor of a gcd filter on $\{E, d, \chi\}$-subset sums, not a count of anything in nature.

The separation is not a stylistic preference. It is a structural necessity. If the formal chain that derives K_4 were contaminated by a single interpretive label—if "proton" appeared where "degree-shifted monomial" suffices, or "electroweak" where "κ^2-scaled" is exact—then a reader could rightly suspect that the construction was steered toward a known target. The filter's credibility depends on the absence of any such steering.

Every quantity computed in this volume is an invariant of K_4 under $\mathrm{Aut}(K_4) \cong S_4$. Whether any of these invariants correspond to quantities measured in a laboratory is a question that belongs entirely to the companion volume *Form*. The one irreducibly interpretive step—which κ^n-scaled correction fraction corresponds to which external sector—is performed there, and only there, with an explicit marking that it is an interpretation rather than a derivation.

This is the red line. Everything below it is K_4 and its survivors. Nothing else.

So, what now begins is the first irreversible pressure test. The question is not whether something can be pulled from the void—it is whether the void can remain unmarked at all. If it can, nothing follows. If it cannot, then what the void already contains is not a choice but a necessity—and the derivation is a sentence the void passes on itself.

Part I

Foundation

The eliminative chain begins with its most radical demand: if the infrastructure is not itself forced, the entire derivation rests on borrowed ground and the specificity of the later survivor carries no weight. Equality, pairing, negation, decidability, and the natural numbers—the tools every later chapter requires—must survive the filter, not precede it.

The stakes are higher than they appear. In standard formal work, the natural numbers are an import—a foundation that the system stands on but never justifies. Here, nature forces a different discipline: the naturals must emerge as the unique survivor of an elimination, or the chain does not begin at all. This is the first instance of a pattern that reaches its extremity in Part V, where the integers, rationals, and reals follow the same path. But the discipline starts here, at the most elementary boundary: the moment the void is examined, it marks itself, and the infrastructure of marking is not optional.

Chapter 2

The Foundation of Necessity

The void must be examined—but the act of examination itself must first be constrained. This is the first step, and the most counterintuitive: before a single distinction can be drawn, every escape route that would make the result dependent on human choice must be sealed. The doors close before the investigation begins.

Consider what happens if any door remains open. A formal system that permits unproven axioms—postulates accepted on faith—gains arbitrary degrees of freedom. Any structure derived from such a system inherits those degrees of freedom. The results would depend on which postulates a human happened to choose, not on what the void demands. So the first door closes: the Agda flag --safe forbids all postulates. Nothing enters this system that is not constructed from within.

The second door concerns identity. In many formal systems, it is taken for granted that all proofs of the same equality are themselves identical—a principle known as Axiom K. This sounds harmless. But it imposes a hidden constraint: it flattens the space of proofs into a single layer. Higher-dimensional structure—where the *way* two things are equal matters, not just *that* they are—is silently collapsed before it can be examined. Since the investigation must remain open to relational complexity at every level, this premature flattening is unacceptable. The flag --without-K prevents it.

The third door concerns self-reference. Without universe stratification, a type could contain itself as a member—an act that immediately produces paradox (Russell's paradox being the most famous instance). Agda's hierarchy of universe levels (Level, Set_ω) prevents this by ensuring that every type lives strictly below the level that quantifies over it. No type can swallow itself.

Three constraints—no postulates, no identity collapse, no self-reference—and none is a design choice. They are the minimal conditions under which a formal system can interrogate the void without contradiction. The module opens under these restrictions.

```
-- § Strict Environment Constraint: No axioms, no postulates, no Axiom K.
module Void where

-- § Stratification primitives are forced to prevent self-reference paradoxes.
open import Agda.Primitive using (Level; lzero; lsuc; _⊔_; Setω)
```

Propositional Equality

With every door sealed, the first question is immediate: when are two things the same?

This is not a philosophical musing. Without a stable notion of equality, no proof can refer to a previous result. No substitution can be performed. No structure can be recognized across contexts. A system without equality is a system where nothing follows from anything—where every statement is an island. That is not logic. That is noise.

So equality must exist. But what is the minimal form it can take? The answer is surprisingly tight. A single constructor suffices: refl, which states that a thing is equal to itself. Nothing more is assumed. From this one fact, the entire machinery of equality—symmetry, transitivity, congruence, substitution—follows by elimination on refl. Pointwise distinct definitions of these eliminators may exist as syntactic terms; their behaviour on the single constructor identifies them up to propositional equality, as the closing lemma of this section makes precise.

Constraint: Without an identity type, no equational rewriting is available; substitution, congruence, and case analysis collapse together. **Construction:** The inductive type _≡_ with the single generator refl is the smallest type-theoretic structure that supports the J-rule. The four eliminators below are defined by pattern-matching on refl alone. **Consequence:** Every equational rewrite available in the development factors through these four operations.

```
-- § Propositional equality: the identity type with unique constructor refl.
infix 4 _≡_

data _≡_ {ℓ : Level} {A : Set ℓ} (x : A) : A → Set ℓ where
 refl : x ≡ x
{-# BUILTIN EQUALITY _≡_ #-}

-- § Symmetry is forced by elimination on refl.
sym : {ℓ : Level} {A : Set ℓ} {x y : A} → x ≡ y → y ≡ x
sym refl = refl

-- § Transitivity is forced by elimination on the first proof.
trans : {ℓ : Level} {A : Set ℓ} {x y z : A} → x ≡ y → y ≡ z → x ≡ z
trans refl q = q

-- § Congruence: equality is invariant under function application.
cong : {ℓ₁ ℓ₂ : Level} {A : Set ℓ₁} {B : Set ℓ₂} (f : A → B) {x y : A} → x ≡ y → f x ≡ f y
cong f refl = refl

-- § Substitution: transport along an equality proof.
subst : {ℓ₁ ℓ₂ : Level} {A : Set ℓ₁} (P : A → Set ℓ₂) {x y : A} → x ≡ y → P x → P y
subst P refl px = px
```

The uniqueness alluded to above takes the following sharp form. Symmetry is the unique inverse: any $q : y \equiv x$ that closes the triangle with $p : x \equiv y$ to the trivial loop coincides with $\mathrm{sym}\, p$.

Constraint: A second symmetry operator, propositionally distinct from sym, would split the equational calculus into incompatible rewrite paths. **Elimination:** Pattern-matching on p reduces $\mathrm{trans}\, p\, q$ to q and $\mathrm{sym}\, p$ to refl; the loop hypothesis is then literally the desired equality. **Consequence:** Every operator inverting equalities through the canonical loop condition is propositionally identified with sym.

```
-- § Symmetry is the unique inverse closing the trivial loop.
sym-unique :
 {ℓ : Level} {A : Set ℓ} {x y : A}
 (p : x ≡ y) (q : y ≡ x) →
 trans p q ≡ refl →
 q ≡ sym p
sym-unique refl q eq = eq
```

Universe Lifting

The stratification imposed in the previous section—universe levels that prevent self-reference—creates an immediate practical problem. A proof living at one level cannot directly interact with a proof living at another. The levels are sealed compartments. Without a controlled passage between them, the system would fragment into isolated strata that cannot communicate.

The passage must satisfy a strict requirement: moving a witness up to a higher level and back down again must return exactly the original witness, unchanged. If the round trip alters anything—introduces noise, loses information, or shifts meaning—then cross-level reasoning becomes unreliable.

Lift embeds a value one level higher with the property that the round trip is faithful. The injectivity lemma proves no information is lost: if two lifted values are equal, the originals were already equal. The universal property below characterises Lift up to isomorphism: every wrapper W with mutually inverse round-trip operations is canonically isomorphic to Lift A.

Constraint: Cross-level reasoning collapses if the lifting introduces noise or fails to be faithful; the elevator must return its passenger unchanged. **Construction:** The inductive wrapper Lift with constructor lift and projection lower is the smallest structure with definitional round-trip on the elevated witness. **Consequence:** Any other faithful wrapper is canonically isomorphic to Lift; in particular two lifted values are equal iff the originals are.

```
-- § Lift embeds a type into the next universe level.
data Lift {ℓ : Level} (A : Set ℓ) : Set (lsuc ℓ) where
 lift : A → Lift A

-- § Lower extracts the embedded value.

; from = λ { (lift a) → wrap a }
; to-from = λ { (lift a) → cong lift (unwrap-wrap a) }
; from-to = λ w → wrap-unwrap w
}
```

Universe-Polymorphic Equality

There is a ceiling in Agda's universe hierarchy: Set_ω, the level that sits above all numbered levels. Statements that quantify over all universe levels—and such statements are unavoidable later—live here.

But the equality type (_≡_) was defined at a specific, bounded level. It cannot operate at Set_ω. This is not a limitation that can be worked around; it is a hard type error. If the gap remains open, then the highest level of the system—the level where the most general statements live—has no notion of identity. Proofs at that level could not be compared, composed, or transported. The top would be lawless.

The solution is forced: replicate the identity type at Set_ω. The replica, _≡ω_, has the same single constructor (reflω) and the same derived operations. Its universal role is captured by the initiality lemma below: every reflexive relation on Set_ω types factors through _≡ω_.

Constraint: The identity type at lower levels does not type-check at Set_ω; without a top-level identity, statements quantifying over all universe levels are unfounded. **Construction:** The inductive type $_ \equiv_\omega _$ with constructor refl_ω is the smallest reflexive relation at Set_ω, equipped with the standard four eliminators. **Consequence:** Every reflexive relation on Set_ω is implied by $_ \equiv_\omega _$; the relation is therefore initial in the category of reflexive Set_ω-relations.

```
-- § Universe-polymorphic equality at Setω.

```

Products and Dependent Pairs

So far, every structure holds a single piece of information. But the moment a statement like "there exists an element with a certain property" must be expressed, two things must be held at once: the element and the proof of its property. Without a way to bundle these together, existential statements are inexpressible. The system can talk about individual objects but cannot witness claims about them.

The product type (A × B) is the simplest response: it holds two independent values side by side. But the more consequential structure is the dependent pair (Σ A B), where the type of the second component depends on the value of the first. This is what makes it possible to say "there exists an a in A such that $B(a)$ holds"—the a and its proof travel together as a single witness. Without dependent pairs, the gap between "for all" and "there exists" cannot be bridged, and half of logic collapses.

Constraint: Existential statements "there exists $a : A$ such that $B(a)$ holds" require simultaneous packaging of a witness and its proof; without dependent pairs, the bridge between universal and existential quantification is missing. **Construction:** The record _×_ packages two independent values; Σ generalises to dependent pairs in which the second component depends on the first. **Consequence:** Every existential argument in the development is realised as an inhabitant of Σ, with _×_ the constant case.

Absurdity and Negation

If the filter described in the introduction is to have any teeth, it must be possible to express that something *cannot* exist. A system that can only affirm—never deny—has no elimination power. It accepts everything. And a system that accepts everything proves nothing.

The empty type ($\bot$) is the formal expression of impossibility: a type with no constructors, and therefore no inhabitants. If you somehow hold a value of type $\bot$, you have a contradiction—and from a contradiction, anything follows. This is $\bot$-elim, the principle of *ex falso quodlibet*: from the impossible, derive whatever you wish.

Negation falls out immediately. To say "A is false" is to say "A leads to a contradiction"—formally, $\neg A$ is the function type $A \to \bot$. No additional negation primitive is needed. Double negation and inequality are then derived forms, not new axioms.

Constraint: A logic that can only affirm has no elimination power; without a formal type of impossibility, the filter has no teeth. **Construction:** The empty type $\bot$ is the inductive type with zero constructors; $\bot$-elim is its eliminator. Negation $\neg A$ is defined as $A \to \bot$; double negation and inequality are derived. **Consequence:** The principle of *ex falso quodlibet* is available; refutations carry the same logical weight as constructions.

```

x ≠ y = ¬ (x ≡ y)
```

Disjoint Union

Pairs express "both A and B." But logic also requires "either A or B"—and it requires knowing *which one*. An untagged alternative—where the two cases are merged without a label—destroys the ability to distinguish them. Case analysis becomes impossible.

The disjoint union ($\mathrm{A} \uplus \mathrm{B}$) solves this by tagging each side: inj_1 marks a witness from the left, inj_2 from the right. Pattern matching can then always determine which case holds. The

Set$_\omega$ variant (_⊎ω_) extends this to the top universe level, for the same reason equality was extended to all levels: every level must carry the full logical vocabulary, or the system has blind spots.

Constraint: Untagged alternatives between two cases destroy the ability to discriminate them under pattern matching. **Construction:** _⊎_ is the inductive sum with constructors inj_1 and inj_2; _⊎ω_ replicates it at *Set*$_\omega$. **Consequence:** Every binary case analysis in the development—including the coverage field of Distinction—is realised as pattern matching on _⊎_.

```

Ontological Primitives

Before the first distinction can be drawn—the primordial cut between "is" and "is not"—the system must be precise about what it means for a type to be interesting enough to cut at all.

A type that contains only one element, where every inhabitant is provably equal to every other, is *contractible*. It has no internal structure. Drawing a distinction within it is meaningless—there is nothing to separate.

At the other extreme, a type that contains at least two provably *different* inhabitants has a genuine internal boundary. This is the minimal precondition for distinction: you cannot cut what has no parts.

These three predicates—contractibility, the existence of a distinct pair, and non-triviality—are the vocabulary the system needs before the first distinction can even be *stated*. They are not deep theorems. They are the definitions without which the question "can this type be cut?" has no formal meaning.

Constraint: The question "can this type be cut?" has no formal meaning until contractibility, distinct-pair existence, and non-triviality are formalised. **Construction:** isContr A asserts a single absorbing centre; HasDistinctPair A asserts the existence of two provably unequal inhabitants; NonTrivial A negates contractibility. **Consequence:** The first distinction can now be stated; the carrier of any inhabited Distinction is non-trivial, as Law 0.4 records.

```
-- § Contractibility: a single center absorbs all inhabitants.
isContr : Set → Set
isContr A = Σ A (λ c → (x : A) → c ≡ x)
```

```
-- § A type has a distinct pair if two inhabitants are provably unequal.
HasDistinctPair : Set → Set
HasDistinctPair A = Σ A (λ a → Σ A (λ b → a ≢ b))

-- § Non-triviality: the type is not contractible.
NonTrivial : Set → Set
NonTrivial A = ¬ (isContr A)
```

The Distinction Record

What, then, is a distinction? Not philosophically—formally. Strip away every detail that is not logically essential: what survives?

A carrier type. Two witnesses in that carrier. A proof that the witnesses are not equal. And a coverage guarantee that every element of the carrier falls into one of these two classes. Together these four fields suffice for the canonical eliminator constructed in the next chapter; the operational necessity of the coverage field in particular is established by the counterexample lemma at the end of this section.

The coverage field admits no weakening into a partial classifier without losing the eliminator: unclassified witnesses would escape every predicate proof. Replacing it with a three-class cover, on the other hand, would introduce a third boundary point—the carrier would no longer be two-class, and the word "distinction" would no longer apply.

Constraint: The development requires a structure that supports a uniform two-case analysis on its carrier; without coverage no such analysis exists. **Construction:** The record Distinction packages a carrier, two designated witnesses, a separation proof, and a coverage classifier into a single Set_1-valued type. **Consequence:** The four fields jointly support the canonical eliminator (Chapter 4); the necessity of the coverage field is exhibited explicitly below.

```
-- § The first distinction: carrier, boundary points, separation, and coverage.
record Distinction : Set1 where
 field
  S    : Set
  ℓ    : S
  r    : S
  ℓ≢r : ℓ ≢ r
  cover : (x : S) → (x ≡ ℓ) ⊎ (x ≡ r)

open Distinction public
```

Necessity of Coverage

The coverage field carries operational content distinct from the separation proof. A hypothetical eliminator schema that would discharge every predicate from boundary witnesses alone—without coverage—is refutable on any carrier strictly larger than two elements. The argument requires a concrete inhabited type with at least three distinguishable members; the four-element vertex type K_4Vertex introduced in Chapter 45 provides one. The corresponding refutation is recorded as Lemma 45 below.

Constraint: Any defence of the coverage field as logically eliminable must explain how a carrier with more than two elements could be discharged from two boundary witnesses alone. **Elimination:** Lemma 45 instantiates the hypothetical schema at K_4Vertex with the predicate that is empty at an off-boundary vertex and produces an inhabitant of $\bot$. **Consequence:** The coverage field cannot be dropped; without it, no eliminator of the kind used throughout the rest of the development exists.

Chapter 3

Non-Vacuity

The record $\mathrm{Distinction}$ now exists as a type. But types can be empty. If no inhabitant of this type can be constructed—if no actual distinction exists—then every law derived from it holds vacuously. "For all distinctions d, $P(d)$" is trivially true when there are no distinctions. The entire formal apparatus would prove everything and say nothing.

This is the empty-ontology loophole, and it must be closed before any subsequent reasoning has force. It is closed from both ends: the opening law blocks the vacuous path forward, and the book's closing theorem confirms the loop from the other direction—any inhabitant of the invariant record already contains a distinction. The loophole has no exit.

Under --safe, postulating a distinction directly is not available. Among the standard barriers (decidability, propositional truncation, double negation), the double-negation form $\neg\neg$ *Distinction* is the weakest assertion that still blocks the vacuous path—and therefore the most parsimonious choice at this stage of the development. It does not exhibit a concrete distinction; it precludes consistent denial of one.

This opening law is deliberately weak. The constructive proof that $\mathrm{Distinction}$ is inhabited arrives in Chapter 5, where $\mathrm{Two\text{-}distinction}$ produces a parameterless witness with no assumptions at all. A second, independent route emerges from measurement (Chapter 51): any binary measurement already carries a distinction kernel in its outcome space. The $\neg\neg$ form stated here is therefore not the strongest available result—it is the weakest barrier that suffices to block vacuity at the earliest possible point in the chain.

A natural objection asks for something stronger still: a proof that *existence itself* requires distinction—that every inhabited type already contains a two-element substructure. In type theory, this claim is simply false. The unit type $\top$ is inhabited by a single element tt, carries no two distinct members, and yet exists without contradiction. The proposition $\forall\,(A : \mathit{Set}).\ A \to \mathit{Distinction}$ is refuted by $A = \top$. Any argument that proceeds from "an object exists without distinction" to "therefore no identity, no reference, no existence claim is possible" collapses at the first step: $\mathrm{tt} \equiv \mathrm{tt}$ is refl, identity is trivial, and reference is unproblematic—all without distinction.

The chain does not need this false theorem. It needs something both weaker and more direct: that $\mathrm{Distinction}$ is freely available as a parameterless construction. $\mathrm{Two\text{-}distinction}$ provides

exactly that. No premise is consumed. No prior existence claim is imported. The type data Two = L | R is definable in every consistent type theory—with or without the axiom of choice, with or without univalence, classically or intuitionistically. Whoever accepts a type theory at all already has D_0.

```
-- § Non-vacuity demands that Distinction cannot be refuted.
record NonVacuityLaw : Set1 where
 field
  nonvacuity : ¬¬ Distinction

open NonVacuityLaw public
```

Law 0.0: Distinction Is Irrefutable

The first law is the simplest and the most important. If ¬ *Distinction* were admissible—if consistent denial of distinction were possible—then every law of the form "for all distinctions d..." would be vacuously true. No elimination would occur. No structure would be forced. The entire investigation would be an elaborate tautology about nothing. Among the standard barriers against vacuity—decidability, propositional truncation, and double negation—the double-negation form is the weakest still admissible under --safe, and is therefore the most parsimonious choice at this stage of the development.

```
-- § Law 0.0: Distinction is irrefutable.
law0-0-nonvacuity : (nv : NonVacuityLaw) → ¬¬ Distinction
law0-0-nonvacuity = nonvacuity
```

Law 0.1: Non-Vacuity Is Non-Eliminability

The non-vacuity law says exactly the same thing in its sharpest form: distinction cannot be eliminated. The negation of distinction is itself refutable. This is not a constructive existence claim—no concrete distinction is in hand—but it is enough to guarantee that every subsequent argument has a non-trivial domain.

```
-- § Law 0.1: NonVacuityLaw is non-eliminability of Distinction.
law0-1-nonvacuity-is-non-eliminability :
 NonVacuityLaw → ¬ (¬ Distinction)
law0-1-nonvacuity-is-non-eliminability = nonvacuity
```

Law 0.2: Distinction Carrier Is Inhabited

Once a distinction exists, its carrier cannot be empty. The boundary witness ℓ is already part of the record—it *is* a member of the carrier by construction. This is not a theorem that requires proof; it is an immediate consequence of what "distinction" means. An empty carrier would have no witnesses, and a structure with no witnesses is no distinction at all.

```
-- § Law 0.2: Distinction carrier is inhabited.
law0-2-inhabited : (d : Distinction) → S d
law0-2-inhabited d = ℓ d
```

Law 0.3: Distinction Carrier Has A Distinct Pair

The carrier does not merely contain an element—it contains two elements that are provably not equal. The boundary witnesses ℓ and r, together with the separation proof $\ell \neq r$, hand us a distinct pair directly from the record. No carrier with fewer than two distinguishable elements can support a distinction.

```
-- § Law 0.3: Distinction carrier has a distinct pair.
law0-3-has-distinct-pair : (d : Distinction) → HasDistinctPair (S d)
law0-3-has-distinct-pair d = (ℓ d , (r d , ℓ≠r d))
```

Law 0.4: Distinction Carrier Is Non-Contractible

A contractible type is one where every element is provably equal to a single center point. If the carrier were contractible, then ℓ and r would both collapse to that center—and therefore to each other. But $\ell \neq r$. Contradiction. Contractibility is dead on arrival.

```
-- § Law 0.4: Distinction carrier is non-contractible.
law0-4-not-contractible : (d : Distinction) → NonTrivial (S d)
law0-4-not-contractible d (c , collapse) =
 ℓ≠r d (trans (sym (collapse (ℓ d))) (collapse (r d)))
```

Law 0.5: Distinct Pair Forces Non-Contractibility

This is the general principle behind the previous law, freed from the specific context of distinction. Whenever *any* type carries a pair of elements known to be unequal, that type cannot be contractible. The center of contraction would identify the pair, contradicting their separation. The proof is identical in structure: transport through the center, arrive at equality, invoke the separation witness.

```
-- § Law 0.5: Distinct pair forces non-contractibility.
law0-5-distinct-pair-forces-nontrivial :
 {A : Set} → HasDistinctPair A → NonTrivial A
law0-5-distinct-pair-forces-nontrivial (a , (b , a≠b)) (c , collapse) =
 a≠b (trans (sym (collapse a)) (collapse b))
```

Law 0.6: Distinction Is Reconstructible From Its Data

If you have a type, two elements of that type, a proof of their inequality, and a coverage function—then you have a distinction. There is no fifth ingredient, no hidden requirement, no gap between "having all the data" and "having the record." The record is exactly its fields, nothing more. This is what makes the formalization honest: the definition conceals no implicit structure.

```
-- § Law 0.6: Distinction is reconstructible from its data.
fromDistinctCovered :
 {S₀ : Set} (a b : S₀) →
 a ≠ b →
```

```
((x : S₀) → (x ≡ a) ⊎ (x ≡ b)) →
 Distinction
fromDistinctCovered {S₀} a b a≠b cov = record
 { S = S₀ ; ℓ = a ; r = b ; ℓ≠r = a≠b ; cover = cov }

law0-6-reconstruction :
 {S₀ : Set} (a b : S₀) →
 (a≠b : a ≠ b) →
 (cov : (x : S₀) → (x ≡ a) ⊎ (x ≡ b)) →
 Distinction
law0-6-reconstruction = fromDistinctCovered
```

Law 0.7: Reconstruction Is Exact

The round trip is lossless. Take a distinction, extract its four components, feed them back into the constructor: the result is definitionally equal to the original. Not propositionally equal—not "there exists a proof of equality"—but definitionally equal, meaning the type checker treats them as the same term without any proof at all. The proof is refl. This is the strongest form of exactness a reconstruction can have.

```
-- § Law 0.7: Reconstruction is exact by definitional equality.
law0-7-reconstruction-exact :
 (d : Distinction) →
 fromDistinctCovered (ℓ d) (r d) (ℓ≠r d) (cover d) ≡ d
law0-7-reconstruction-exact d = refl
```

The distinction record is stable under reconstruction: it can be decomposed into its four components and reassembled without loss. This is the sharpest form of structural identity the type system can express. The object is not merely described—it is locked.

Chapter 4

Elimination and Classification

The distinction record is established. What can be done with it?

The answer is surprisingly constrained. Two-class coverage—the guarantee that every element of the carrier equals ℓ or r—does not merely partition the carrier. It forces a radical compression of the entire function space. Any endomorphism $f : S \to S$ is completely determined by two values: $f(\ell)$ and $f(r)$. Each of these values is itself forced into one of two classes. So the total number of endomorphisms is at most $2 \times 2 = 4$. Not approximately. Exactly.

This chapter traces that compression from its source (coverage) to its consequence (the complete four-case classification that constitutes K_4).

Two-Class Coverage

Law 1.1: Carrier Coverage Is Two-Class

The coverage field is not a bonus feature of the distinction record—it is the engine that drives everything that follows. Without it, the carrier might contain elements that are neither ℓ nor r: unclassified witnesses that escape the boundary structure. With it, every element is nailed down. There is nowhere to hide.

Constraint: Without two-class coverage, unclassified witnesses escape every predicate proof; the eliminator of the next subsection would be ill-formed. **Elimination:** Coverage forces every carrier inhabitant to lie in $\{\ell, r\}$; the alternative—a third unclassified element—is ruled out by the cover field directly. **Consequence:** The four-case endomorphism classification of Section 4 compresses the function space to exactly four maps.

```
– § Law 1.1: Carrier coverage is two-class.
law1-1-cover : (d : Distinction) → (x : S d) → (x ≡ ℓ d) ⊎ (x ≡ r d)
law1-1-cover = cover
```

Two-class coverage forces the first structural milestone: every surviving witness lies on one of two boundary classes. Figure 4.1 fixes this collapse as a two-node distinction diagram.

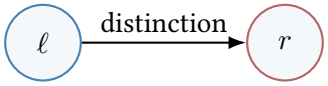

Figure 4.1: First distinction: two boundary witnesses forced by two-class coverage.

Law 1.2: Elimination Is Forced By Coverage

Coverage has a powerful consequence: it supplies a canonical eliminator. For any predicate P on the carrier, if $P(\ell)$ and $P(r)$ both hold, then $P(x)$ holds for every x. The proof is mechanical: ask cover which class x belongs to, then substitute the appropriate witness. The two boundary cases exhaust the carrier; the uniqueness lemma below records that any two such eliminators agreeing on the boundary are pointwise identified.

Constraint: A second eliminator that agrees with Distinction-elim on the boundary but disagrees somewhere on the interior would split the case-analysis calculus on Distinction into incompatible reductions. **Elimination:** Case-splitting on cover $d\,x$ rewrites both eliminators along the same identity; their boundary equations then identify the values, and the rewrites compose to the desired pointwise equality. **Consequence:** The non-dependent eliminator of Distinction is unique up to propositional equality; its dependent counterpart inherits this uniqueness up to transport.

```
-- § The canonical eliminator for a distinction carrier.

    (trans (e₁ r bℓ br)
    (trans (sym (e₂ r bℓ br))
           (cong (e₂ bℓ br) (sym p))))
```

Duality

Once the carrier has exactly two classes, there is exactly one nontrivial thing you can do to it: swap the two sides. Send ℓ to r and r to ℓ. This is the dual map. It is not one permutation among many—it is the unique non-identity permutation that a two-element carrier admits, as established formally in Law 1.11 (aut-sound) below.

The critical property is involutivity: applying the swap twice returns to the starting point. This is not merely expected—it is forced. If the double application landed anywhere other than the original, it would produce a third element or violate coverage. Neither is possible. So duality is an involution, and this fact is proved by exhaustive case analysis on both boundary witnesses.

Constraint: A second non-identity permutation would generate an orbit of length three or more; the carrier has only two elements. **Elimination:** The double application dual(dual(x)) cannot land outside $\{\ell, r\}$ (no third element exists by coverage) and cannot remain at the swapped point (separation contradicts coverage in the off-diagonal cases). **Consequence:** Distinction-dual is involutive (Law 1.3), and Law 1.11 confirms it is the unique non-identity permutation.

```
-- § The dual map: swap boundary cases.
Distinction-dual : (d : Distinction) → S d → S d
Distinction-dual d x with cover d x
... | inj₁ _ = r d
... | inj₂ _ = ℓ d

-- § Duality is involutive by exhaustive case analysis.
Distinction-dual-involutive :
 (d : Distinction) →
 (x : S d) →
 Distinction-dual d (Distinction-dual d x) ≡ x
Distinction-dual-involutive d =
 Distinction-elim d proof-ℓ proof-r
 where
  proof-ℓ : Distinction-dual d (Distinction-dual d (ℓ d)) ≡ ℓ d
  proof-ℓ with cover d (ℓ d)
  ... | inj₂ ℓ≡r = ⊥-elim ((ℓ≠r d) ℓ≡r)
  ... | inj₁ _ with cover d (r d)
  ... | inj₁ r≡ℓ = ⊥-elim ((ℓ≠r d) (sym r≡ℓ))
  ... | inj₂ _ = refl

  proof-r : Distinction-dual d (Distinction-dual d (r d)) ≡ r d
  proof-r with cover d (r d)
  ... | inj₁ r≡ℓ = ⊥-elim ((ℓ≠r d) (sym r≡ℓ))
  ... | inj₂ _ with cover d (ℓ d)
```

```
... | inj₂ ℓ≡r = ⊥-elim ((ℓ≠r d) ℓ≡r)
... | inj₁ _ = refl
```

Law 1.3: Duality Is An Involution

If the dual map were not involutive, it would generate an orbit of length three or more—but the carrier has only two elements. There is no room. The double application must return to the original, and that is exactly what the type checker confirms.

```
-- § Law 1.3: Duality is an involution.
law1-3-dual-involutive :
 (d : Distinction) →
 (x : S d) →
 Distinction-dual d (Distinction-dual d x) ≡ x
law1-3-dual-involutive = Distinction-dual-involutive
```

Pointwise Equality

When are two endomorphisms the same? The answer is forced by the elimination structure already established. Since every carrier element is determined by its boundary class, and every endomorphism is determined by what it does to the boundary, two endomorphisms agree iff they agree on every input. The universal-property lemma below records this in standard form: pointwise equality is initial among the relations on the function space that respect the boundary.

Constraint: Intensional definitions of endomorphisms can differ syntactically without producing different outputs; a comparison sensitive to such differences is too fine for the present development. **Construction:** _≐_ compares two functions by demanding pointwise propositional equality on the entire domain. **Consequence:** The classification of Chapter 4 is up to _≐_; the universal-property lemma below shows that no coarser comparison respects the boundary.

```
-- § Pointwise equality of functions.
infix 4 _≐_
_≐_ : {ℓ₁ ℓ₂ : Level} {A : Set ℓ₁} {B : Set ℓ₂} → (A → B) → (A → B) → Set (ℓ₁ ⊔ ℓ₂)
_≐_ {A = A} f g = (x : A) → f x ≡ g x

-- § The identity function.
id : {A : Set} → A → A
id x = x

-- § Pointwise equality is initial among boundary-respecting comparisons of endomorphisms.
≐-universal :
 (d : Distinction)
 (R : (S d → S d) → (S d → S d) → Set) →
 ({f g : S d → S d} → R f g → f (ℓ d) ≡ g (ℓ d)) →
 ({f g : S d → S d} → R f g → f (r d) ≡ g (r d)) →
 {f g : S d → S d} → R f g → f ≐ g
≐-universal d R agree-ℓ agree-r {f} {g} rfg x with cover d x
... | inj₁ p = trans (cong f p) (trans (agree-ℓ rfg) (cong g (sym p)))
... | inj₂ p = trans (cong f p) (trans (agree-r rfg) (cong g (sym p)))
```

Four-Case Endomorphism Classification

Now the compression becomes visible. An endomorphism $f : S \to S$ sends each boundary witness to some element of the carrier. But every element of the carrier is either ℓ or r. So $f(\ell)$ is either ℓ or r, and $f(r)$ is either ℓ or r. That gives exactly four possibilities:

- $f(\ell) = \ell$ and $f(r) = \ell$: the constant-left map.
- $f(\ell) = r$ and $f(r) = r$: the constant-right map.
- $f(\ell) = \ell$ and $f(r) = r$: the identity.
- $f(\ell) = r$ and $f(r) = \ell$: the dual.

There is no fifth case. The four labels below name these survivors.

Constraint: Coverage forces every carrier element into the boundary $\{\ell, r\}$, and boundary distinctness $\ell \neq r$ forbids identifying the two. Any endomorphism is therefore pinned down by its two boundary outputs, each ranging over a two-element set.

Elimination: Two boundary outputs in a two-element set yield $2 \times 2 = 4$ possibilities. Every other count is annihilated: a fifth case would demand a third boundary class (forbidden by coverage) or a third boundary value (forbidden by $\ell \neq r$); a third case would demand collapsing two of the four into one, contradicting boundary distinctness applied at the boundary outputs.

Consequence: The four labels below are not chosen; they are what survives. The data type EndoCase is the type-theoretic image of this elimination, and its four constructors carry no further freedom.

```
– § The four-case classification of endomorphisms.
data EndoCase : Set where
 case-constL : EndoCase
 case-constR : EndoCase
 case-id     : EndoCase
 case-dual : EndoCase
```

Figure 4.2 makes the pressure visible in the negative direction. A three-vertex closure cannot survive this classification, because one of the four mutually distinct cases is always left outside. The triangle is therefore not a weaker rival to K_4; it is the first unstable alternative that the four-case verdict destroys.

The K_4 Classification Module

The four cases are not yet a classification—they are just labels. A proper classification requires three things: an *interpretation* that turns each label into an actual endomorphism, a *classifier* that assigns a label to any given endomorphism, and proofs that these two operations are inverses of each other. Soundness (classify then interpret recovers the original) and injectivity (distinct labels produce distinct behavior) together force uniqueness: every endomorphism receives exactly one label, and no two labels describe the same map.

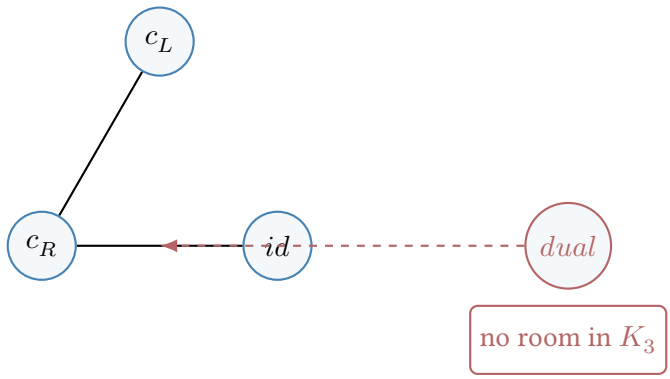

Figure 4.2: Why K_3 fails: four mutually distinct endomorphism cases cannot close on a three-vertex graph. One case is always forced outside.

The module K_4 assembles all of this in one place. It is parameterized by a distinction d, because the classification depends on the specific boundary witnesses.

Step 1: Endo type and pointwise equivalence. The endomorphism type and its equivalence relation are forced by the carrier.

```
-- § K₄ endomorphism algebra: classify, interpret, and verify.
module K₄ (d : Distinction) where
 Endo : Set
 Endo = S d → S d

 ≐-refl : {f : Endo} → f ≐ f
 ≐-refl x = refl

 ≐-sym : {f g : Endo} → f ≐ g → g ≐ f
 ≐-sym p x = sym (p x)

 ≐-trans : {f g h : Endo} → f ≐ g → g ≐ h → f ≐ h
 ≐-trans p q x = trans (p x) (q x)
```

Step 2: The four canonical endomorphisms. Two-class coverage forces exactly four surviving endomorphisms: constant-left, constant-right, identity, and dual. The dual exchanges the two boundary witnesses; its boundary behavior is verified by case analysis against cover.

```
-- § Constant-left endomorphism.
constL : Endo
constL _ = ℓ d

-- § Constant-right endomorphism.
constR : Endo
constR _ = r d

-- § The dual endomorphism.
dual : Endo
dual = Distinction-dual d

-- § Dual sends ℓ to r.
dual-ℓ : dual (ℓ d) ≡ r d
dual-ℓ with cover d (ℓ d)
```

```
... | inj₁ _ = refl
... | inj₂ ℓ≡r = ⊥-elim ((ℓ≠r d) ℓ≡r)

-- § Dual sends r to ℓ.
dual-r : dual (r d) ≡ ℓ d
dual-r with cover d (r d)
... | inj₁ r≡ℓ = ⊥-elim ((ℓ≠r d) (sym r≡ℓ))
... | inj₂ _ = refl
```

Step 3: Interpretation and classification. Each case label is interpreted as one of the four canonical endomorphisms. Conversely, every endofunction is classified by its boundary outputs into one of the four cases.

```
-- § Interpret a case label as an endofunction.
interpret : EndoCase → Endo
interpret case-constL = constL
interpret case-constR = constR
interpret case-id     = id
interpret case-dual = dual

-- § Classify an endofunction by its boundary outputs.
classify : Endo → EndoCase
classify f with cover d (f (ℓ d)) | cover d (f (r d))
... | inj₁ _ | inj₁ _ = case-constL
... | inj₂ _ | inj₂ _ = case-constR
... | inj₁ _ | inj₂ _ = case-id
... | inj₂ _ | inj₁ _ = case-dual
```

Step 4: Soundness of classification. Classification followed by interpretation recovers the original endofunction at both boundary witnesses. The pointwise proof is assembled from the two boundary cases via the carrier eliminator.

```
-- § Soundness at ℓ: interpretation recovers the value at ℓ.
sound-at-ℓ : (f : Endo) → interpret (classify f) (ℓ d) ≡ f (ℓ d)
sound-at-ℓ f with cover d (f (ℓ d)) | cover d (f (r d))
... | inj₁ fl≡ℓ | inj₁ _ = sym fl≡ℓ
... | inj₂ fl≡r | inj₂ _ = sym fl≡r
... | inj₁ fl≡ℓ | inj₂ _ = sym fl≡ℓ
... | inj₂ fl≡r | inj₁ _ = trans dual-ℓ (sym fl≡r)

-- § Soundness at r: interpretation recovers the value at r.
sound-at-r : (f : Endo) → interpret (classify f) (r d) ≡ f (r d)
sound-at-r f with cover d (f (ℓ d)) | cover d (f (r d))
... | inj₁ _ | inj₁ fr≡ℓ = sym fr≡ℓ
... | inj₂ _ | inj₂ fr≡r = sym fr≡r
... | inj₁ _ | inj₂ fr≡r = sym fr≡r
... | inj₂ _ | inj₁ fr≡ℓ = trans dual-r (sym fr≡ℓ)

-- § Soundness: classification followed by interpretation recovers behavior.
classify-sound : (f : Endo) → interpret (classify f) ≐ f
classify-sound f x = Distinction-elim d (sound-at-ℓ f) (sound-at-r f) x
```

Step 5: Boundary determination and injectivity. Endofunctions are determined by their boundary values alone (via the eliminator). Interpretation is injective: distinct case labels force distinct boundary behavior, so the 4×4 case matrix either produces refl or derives absurdity from $\ell \neq r$.

```
-- § Endofunctions are determined by their boundary values.
endo-determined :
 (f g : Endo) →
 f (ℓ d) ≡ g (ℓ d) →
 f (r d) ≡ g (r d) →
 f ≐ g
endo-determined f g eqℓ eqr x = Distinction-elim d eqℓ eqr x

-- § Interpretation is injective: distinct cases produce distinct behavior.
interpret-injective :
 (c c' : EndoCase) →
 interpret c ≐ interpret c' →
 c ≡ c'
interpret-injective case-constL case-constL _ = refl
interpret-injective case-constL case-constR p = ⊥-elim ((ℓ≠r d) (p (ℓ d)))
interpret-injective case-constL case-id    p = ⊥-elim ((ℓ≠r d) (p (r d)))
interpret-injective case-constL case-dual  p =
 ⊥-elim ((ℓ≠r d) (trans (p (ℓ d)) dual-ℓ))

interpret-injective case-constR case-constL p =
 ⊥-elim ((ℓ≠r d) (sym (p (ℓ d))))
interpret-injective case-constR case-constR _ = refl
interpret-injective case-constR case-id    p =
 ⊥-elim ((ℓ≠r d) (sym (p (ℓ d))))
interpret-injective case-constR case-dual p =
 ⊥-elim ((ℓ≠r d) (sym (trans (p (r d)) dual-r)))

interpret-injective case-id    case-constL p =
 ⊥-elim ((ℓ≠r d) (sym (p (r d))))
interpret-injective case-id    case-constR p = ⊥-elim ((ℓ≠r d) (p (ℓ d)))
interpret-injective case-id    case-id     _ = refl
interpret-injective case-id    case-dual   p =
 ⊥-elim ((ℓ≠r d) (trans (p (ℓ d)) dual-ℓ))

interpret-injective case-dual case-constL p =
 ⊥-elim ((ℓ≠r d) (sym (trans (sym (dual-ℓ)) (p (ℓ d)))))
interpret-injective case-dual case-constR p =
 ⊥-elim ((ℓ≠r d) (trans (sym (dual-r)) (p (r d))))
interpret-injective case-dual case-id      p =
 ⊥-elim ((ℓ≠r d) (sym (trans (sym (dual-ℓ)) (p (ℓ d)))))
interpret-injective case-dual case-dual    _ = refl
```

Step 6: Classification uniqueness. Soundness and injectivity together force that the case label assigned by classify is unique.

```
-- § Classification is unique: the label is forced by soundness + injectivity.
classify-unique : (f : Endo) → (c : EndoCase) → interpret c ≐ f → c ≡ classify f
classify-unique f c c≐f =
 interpret-injective c (classify f) (≐-trans c≐f (≐-sym (classify-sound f)))
```

Step 7: The classifier is a left-inverse of interpretation. Plug $f := \mathit{interpret}\, c$ into uniqueness; the witness is $\mathit{interpret}\, c \mathrel{\dot{=}} \mathit{interpret}\, c$, which is reflexivity. The label round-trips through interpretation and classification without loss.

```
– § Classify followed by interpret followed by classify recovers the label.
classify-interpret : (c : EndoCase) → classify (interpret c) ≡ c
classify-interpret c = sym (classify-unique (interpret c) c ≐-refl)
```

Step 8: Endomorphisms modulo $\dot{=}$ form a four-element set. The two round-trips together exhibit EndoCase as the quotient of Endo by pointwise equivalence. The bijection record below packages all four required laws—surjectivity (classify-sound), uniqueness (classify-unique), the left-inverse round-trip (classify-interpret), and the right-inverse round-trip up to $\dot{=}$ (classify-sound again, restated as the right inverse).

```
– § The bijection between EndoCase and (Endo / ≐).
record EndoCase-bijection : Set where
 field
  to        : Endo → EndoCase
  from      : EndoCase → Endo
  to-from   : (c : EndoCase) → to (from c) ≡ c
  from-to   : (f : Endo) → from (to f) ≐ f
  to-unique : (f : Endo) → (c : EndoCase) → from c ≐ f → c ≡ to f

k4-bijection : EndoCase-bijection
k4-bijection = record
 { to        = classify
 ; from      = interpret
 ; to-from   = classify-interpret
 ; from-to   = classify-sound
 ; to-unique = classify-unique
 }
```

Mutual Distinctness of Cases

The four case labels must remain genuinely different—no two of them may be identified. The labels are constructors of a data type, and Agda's pattern matching confirms that no constructor equals any other. The six pairwise inequalities are all proved by the absurd pattern (): there is simply no way to build a proof that, say, case-constL equals case-id. The type is empty.

```
– § All four EndoCase constructors are pairwise distinct.
EndoCase-distinct :
 (case-constL ≡ case-constR → ⊥) ×
 (case-constL ≡ case-id     → ⊥) ×
 (case-constL ≡ case-dual   → ⊥) ×
 (case-constR ≡ case-id     → ⊥) ×
 (case-constR ≡ case-dual   → ⊥) ×
 (case-id ≡ case-dual       → ⊥)
EndoCase-distinct =
 (λ ()) ,
 ((λ ()) ,
  ((λ ()) ,
   ((λ ()) ,
    ((λ ()) ,
     (λ ))))))
```

Top-Level Classification Witnesses

The local module laws force exported witnesses of soundness and uniqueness. These witnesses are thin wrappers—they add no new content, only accessibility. The classification lives inside the parameterized module K_4; to use it in later chapters, we export soundness and uniqueness at the top level.

```
-- § Top-level K₄ soundness witness.
k4-classification-sound :
 (d : Distinction) →
 (f : S d → S d) →
 Σ EndoCase (λ c → K₄.interpret d c ≐ f)
k4-classification-sound d f = K₄.classify d f , K₄.classify-sound d f

-- § Top-level K₄ uniqueness witness.
k4-classification-unique :
 (d : Distinction) →
 (f : S d → S d) →
 (c₁ c₂ : EndoCase) →
 K₄.interpret d c₁ ≐ f →
 K₄.interpret d c₂ ≐ f →
 c₁ ≡ c₂
k4-classification-unique d f c₁ c₂ p₁ p₂ =
 K₄.interpret-injective d c₁ c₂ (K₄.≐-trans d p₁ (K₄.≐-sym d p₂))
```

Law 1.4: Endo(S) Classifies Into Exactly Four Cases

Every endomorphism on a distinction carrier receives a label from the four-case type. The classifier inspects the two boundary outputs and assigns the unique matching case. No endomorphism escapes classification.

```
-- § Law 1.4: Endo(S) classifies into exactly four cases.
law1-4-classify : (d : Distinction) → (S d → S d) → EndoCase
law1-4-classify d = K₄.classify d
```

Law 1.5: Classification Is Sound

Soundness means that the round trip works: classify an endomorphism, interpret the resulting label, and you get back a function that agrees with the original at every point. This is not a design goal—it is forced by the fact that classification reads off the boundary values and interpretation plugs them back in.

```
-- § Law 1.5: Classification is sound.
law1-5-classify-sound : (d : Distinction) → (f : S d → S d) → K₄.interpret d (K₄.classify d f) ≐ f
law1-5-classify-sound d f = snd (k4-classification-sound d f)
```

Law 1.6: Endo Is Determined By Boundary Values

If two endomorphisms agree on ℓ and agree on r, they agree everywhere. This is a direct consequence of coverage: every carrier element is either ℓ or r, so agreement on those two points

leaves no room for disagreement anywhere else. The interior of the carrier is empty—there are no hidden witnesses where the two maps could diverge.

```
-- § Law 1.6: Endo is determined by boundary values.
law1-6-endo-determined :
 (d : Distinction) →
 (f g : S d → S d) →
 f (ℓ d) ≡ g (ℓ d) →
 f (r d) ≡ g (r d) →
 f ≐ g
law1-6-endo-determined d = K₄.endo-determined d
```

Law 1.7: Classification Is Unique

If a case label c interprets to a function that agrees pointwise with f, then c must be exactly the label that the classifier assigns to f. The proof chains soundness (the classifier's label also interprets correctly) with injectivity (two labels interpreting to the same function must be equal). There is no ambiguity, no alternative labeling. The classification is canonical.

```
-- § Law 1.7: Classification is unique.
law1-7-classify-unique :
 (d : Distinction) →
 (f : S d → S d) →
 (c : EndoCase) →
 K₄.interpret d c ≐ f →
 c ≡ K₄.classify d f
law1-7-classify-unique d f c p =
 k4-classification-unique d f c (fst (k4-classification-sound d f)) p (snd (k4-classification-sound d f))
```

Law 1.8: Classification Is a Bijection

Soundness exhibits the classifier as a right-inverse of interpretation up to pointwise equivalence. The previous law fixes uniqueness on case labels. The remaining direction is forced: interpret a label, classify the result, and the original label is recovered exactly. Together, the four laws—classify (1.4), sound (1.5), boundary determination (1.6), unique (1.7)—and this round-trip law constitute a complete bijection between EndoCase and the quotient $Endo/\ \mathring{=}$. The four-case structure is therefore not a convenient labelling; it is the cardinality of the quotient.

Constraint: A classification that is sound but not invertible would leave room for distinct labels to denote the same equivalence class, defeating the purpose of the four cases. The bijection forecloses this.

Construction: The left-inverse $classify \circ interpret = id$ is forced by uniqueness applied to the trivial witness $interpret\, c \mathring{=} interpret\, c$.

Consequence: Every endomorphism of every distinction carrier lies in exactly one of the four equivalence classes. No fifth class can be added without contradicting either coverage or boundary distinctness.

```
-- § Law 1.8: classify ∘ interpret = id at the case-label level.
law1-8-classify-interpret :
 (d : Distinction) →
```

```
(c : EndoCase) →
 K₄.classify d (K₄.interpret d c) ≡ c
law1-8-classify-interpret d = K₄.classify-interpret d
```

Exhaustive classification reaches the second structural milestone here. Figure 4.3 fixes the unique four-case closure as the complete graph K_4.

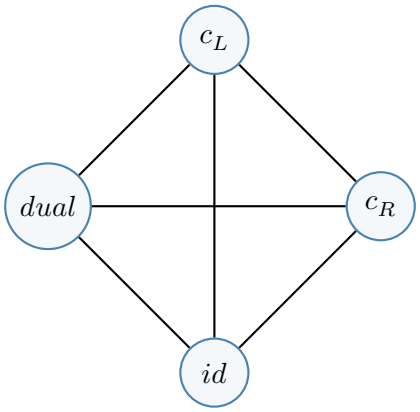

Figure 4.3: Exhaustive four-case endomorphism classification closes as the complete graph K_4.

Chapter 5

Two Normal Form

The classification is complete: every endomorphism falls into one of four cases. But the carrier itself—the type S in the distinction record—is still abstract. Coverage fixes the carrier to two boundary classes, but does not yet fix it to the canonical two-element type. "Having two boundary classes" and "being the canonical two-element type" are different statements. This chapter closes the gap.

The key insight is that coverage forces a canonical isomorphism between any distinction carrier and a concrete two-element type Two. The maps in both directions are uniquely determined by the boundary witnesses, the round trips are identity, and the only remaining freedom is a binary choice: whether ℓ maps to L or to R? That choice is the orientation, and there are exactly two of them. The same compression applies to automorphisms: the only self-equivalences of a distinction are the identity and the dual.

The Two Type

The canonical two-element type has two constructors—L and R—that are provably distinct and exhaustively cover the type. This is the simplest possible distinction. It serves as the solved form: the concrete representative to which every abstract distinction carrier is isomorphic.

```
-- § The canonical two-element type.
data Two : Set where
  L : Two
  R : Two

-- § L and R are distinct.
Two-L≠R : L ≠ R
Two-L≠R ()

-- § Exhaustive two-class coverage for Two.
Two-cover : (x : Two) → (x ≡ L) ⊎ (x ≡ R)
Two-cover L = inj₁ refl
Two-cover R = inj₂ refl

-- § Two forms a canonical Distinction.
Two-distinction : Distinction
Two-distinction = record
```

```
{ S     = Two
; ℓ     = L
; r     = R
; ℓ≠r = Two-L≠R
; cover = Two-cover
}
```

This definition settles the existence question that Chapter 3 deliberately left open. Two-distinction is a parameterless, fully constructive inhabitant of Distinction—no assumptions, no function arguments, no postulates. The ¬¬ *Distinction* barrier that blocked vacuity is upgraded to direct constructive existence: $\lambda\, f \to f$ *Two-distinction* discharges the double negation trivially. Every subsequent chapter inherits this witness.

Distinction Isomorphism

Comparing two distinctions requires a notion of structural equivalence. A *distinction isomorphism* is a pair of maps between the carriers that are mutual inverses and that preserve the boundary witnesses: ℓ maps to ℓ and r maps to r. A weaker notion—*distinction equivalence*—drops the boundary requirement and retains only the inverse laws. The weaker notion is what orientation and automorphism classification will use, since those questions ask precisely whether the boundary is preserved or swapped.

```
– § Boundary-preserving isomorphism between distinctions.

 }
```

Canonical Two Maps

The isomorphism between any distinction carrier and Two writes itself. The forward map toTwo sends ℓ to L and r to R—determined by coverage. The backward map fromTwo reverses this. The round-trip proofs are forced by the eliminator: there is exactly one way to verify that the composition is the identity, and the type checker accepts it.

```
-- § The canonical boundary-preserving map to Two.

toTwo-fromTwo : (d : Distinction) → (t : Two) → toTwo d (fromTwo d t) ≡ t
toTwo-fromTwo d L = toTwo-ℓ d
toTwo-fromTwo d R = toTwo-r d
```

Law 1.8: Every Distinction Is Isomorphic To Two

This is the normal form theorem. Every distinction—regardless of how its carrier was originally defined—is boundary-preserving isomorphic to the canonical Two distinction. The proof assembles the maps and round-trip verifications from the previous section into a single record. There is nothing to choose; every field is forced.

```
-- § Law 1.8: Every distinction is isomorphic to Two.
two-normal-form : (d : Distinction) → DistinctionIso d Two-distinction
two-normal-form d = record
 { to      = toTwo d
 ; from    = fromTwo d
 ; to-from = toTwo-fromTwo d
 ; from-to = fromTwo-toTwo d
```

```
; to-ℓ  = toTwo-ℓ d
; to-r  = toTwo-r d
}

law1-8-two-normal-form : (d : Distinction) → DistinctionIso d Two-distinction
law1-8-two-normal-form = two-normal-form
```

Orientation

An equivalence between a distinction and Two must send the two boundary witnesses to distinct images—otherwise the inverse map would identify ℓ and r, contradicting their separation. The images are elements of Two, which has only two inhabitants. So there are exactly two possibilities: send ℓ to L (preserve) or send ℓ to R (swap). No third option exists.

```
-- § The swap map on Two.
swapTwo : Two → Two
swapTwo L = R
swapTwo R = L

-- § Swap is involutive.
swapTwo-involutive : (t : Two) → swapTwo (swapTwo t) ≡ t
swapTwo-involutive L = refl
swapTwo-involutive R = refl

... | inj₁ _ | inj₂ _ = orient-preserve
... | inj₂ _ | inj₁ _ = orient-swap
```

Automorphisms

An automorphism of a distinction is a self-equivalence: a pair of maps from the carrier to itself that are mutual inverses. The inverse law forces injectivity, and injectivity forces the boundary images to remain distinct (since $\ell \neq r$ would be violated otherwise). With only two elements in the carrier, the only injective endomorphisms are the identity and the swap. That is the complete automorphism group of any distinction: exactly two elements, id and dual.

```
-- § Automorphism of a distinction.
Aut : Distinction → Set1
Aut d = DistinctionEquiv d d

-- § Automorphism transport is injective.
to-injective : (d : Distinction) → (a : Aut d) → {x y : S d} → to a x ≡ to a y → x ≡ y
to-injective d a {x} {y} eq =
 trans (sym (from-to a x)) (trans (cong (from a) eq) (from-to a y))

-- § Automorphism images at boundary points are distinct.
to-ℓ≠to-r : (d : Distinction) → (a : Aut d) → to a (ℓ d) ≠ to a (r d)
to-ℓ≠to-r d a eq = ℓ≠r d (to-injective d a eq)

-- § Dual boundary lemma: dual sends ℓ to r.
Distinction-dual-ℓ : (d : Distinction) → Distinction-dual d (ℓ d) ≡ r d
Distinction-dual-ℓ d with cover d (ℓ d)
... | inj₁ _    = refl
```

```
... | inj₂ ℓ≡r = ⊥-elim ((ℓ≠r d) ℓ≡r)

-- § Dual boundary lemma: dual sends r to ℓ.
Distinction-dual-r : (d : Distinction) → Distinction-dual d (r d) ≡ ℓ d
Distinction-dual-r d with cover d (r d)
... | inj₂ _     = refl
... | inj₁ r≡ℓ = ⊥-elim ((ℓ≠r d) (sym r≡ℓ))

-- § Automorphism classification: exactly id or dual.
Aut-sound :
 (d : Distinction) →
 (a : Aut d) →
 (to a ≐ id) ⊎ (to a ≐ Distinction-dual d)
Aut-sound d a with cover d (to a (ℓ d)) | cover d (to a (r d))
... | inj₁ tℓ≡ℓ | inj₁ tr≡ℓ = ⊥-elim (to-ℓ≠to-r d a (trans tℓ≡ℓ (sym tr≡ℓ)))
... | inj₂ tℓ≡r | inj₂ tr≡r = ⊥-elim (to-ℓ≠to-r d a (trans tℓ≡r (sym tr≡r)))
... | inj₁ tℓ≡ℓ | inj₂ tr≡r =
 inj₁ (Distinction-elim d tℓ≡ℓ tr≡r)
... | inj₂ tℓ≡r | inj₁ tr≡ℓ =
 inj₂ (Distinction-elim d
  (trans tℓ≡r (sym (Distinction-dual-ℓ d)))
  (trans tr≡ℓ (sym (Distinction-dual-r d))))
```

Automorphism classification reaches the third structural milestone here. Figure 5.1 fixes the symmetry action as a permutation of the four case witnesses.

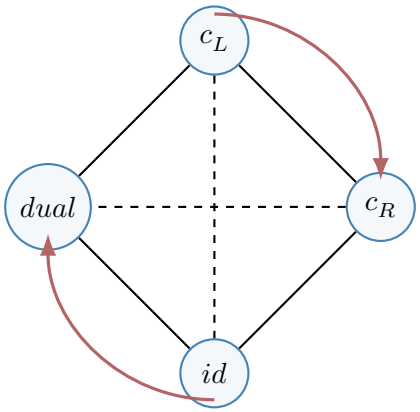

Figure 5.1: Automorphism action on the four-case witness space: preserve and swap survive as the only orbit structure.

Law 1.9: The Two Isomorphism Is Unique

Any boundary-preserving map from a distinction carrier to Two must agree with the canonical map toTwo. The proof is immediate from the eliminator: since the map is determined by its values at ℓ and r, and those values are fixed by the boundary-preservation requirement, there is exactly one such map. The same holds for the backward direction.

```

Law 1.10: Two Normal Form Has Exactly Two Orientations

Every equivalence to Two is either the canonical boundary-preserving map or the swap. The proof checks the image of ℓ: it is either L or R. If L, the map agrees with toTwo. If R, it agrees with toTwo-swap. There is no third possibility, because Two has no third element.

```

Law 1.11: Automorphisms Are Exactly id Or dual

The boundary behavior of any automorphism is forced into one of two patterns: fix both boundaries (identity) or swap both (dual). Any other combination—fixing one and moving the other—would produce a non-injective map, which contradicts the inverse law.

```
-- § Law 1.11: Automorphisms are exactly id or dual.
law1-11-Aut-sound :
 (d : Distinction) →
 (a : Aut d) →
 (to a ≐ id) ⊎ (to a ≐ Distinction-dual d)
law1-11-Aut-sound = Aut-sound
```

Law 1.12: Two-Orientation Classification Is Sound And Unique

The orientation classifier assigns every equivalence to Two one of two labels: case-preserve or case-swap. Soundness: the assigned label interprets back to a map that agrees pointwise with the original equivalence. Uniqueness: no equivalence can receive two different labels, because that would force $L = R$ in Two.

```

Law 1.13: Automorphism Classification Is Sound And Unique

The same structure holds for automorphisms. Every self-equivalence receives exactly one label—case-id or case-dual—and that label is forced by the boundary behavior. If two different labels could describe the same automorphism, their interpretations would agree pointwise, which would force $\ell = r$ via the boundary lemmas. Contradiction eliminates every unsound or non-unique automorphism witness.

```

Two-Class Coverage Without Definitional Equality

The preceding classification relies on propositional equality ≡ as the notion of sameness. Some contexts require coverage with respect to a weaker equivalence relation ≈ that is reflexive, symmetric, and transitive but not necessarily definitional. The record DistinctionClass captures this: it carries a carrier, two separated boundary witnesses, an equivalence relation, and exhaustive coverage under that relation. This weakening does not gain expressive power—it broadens the range of carriers that can be recognized as distinctions without altering the classification theory.

```

Presentation Uniqueness

The four-case classification is canonical, yet a rival presentation could in principle be advanced: a different type X with its own interpretation and classification functions. No alternative type can differ structurally from EndoCase and remain total, sound, and injective—the round-trip via the canonical classifier collapses every candidate to the same isomorphism class. The witness is constructed explicitly below.

Constraint: A rival presentation X must (i) supply a label for every endomorphism (totality), (ii) interpret each label back to its endomorphism (soundness), and (iii) separate distinct labels by distinct interpretations (injectivity). These three are exactly the data of EndoPresentation.

Construction: The forward map sends $x : X$ through interpretation and then through K.classify; the backward map sends c : EndoCase through K.interpret and then through the rival classifier. Round-trip on the EndoCase side closes by K.classify-unique applied to the rival's soundness witness; round-trip on the X side closes by the rival's injectivity applied to the chained soundness equalities. Both directions are forced; the SetIso record packages the witness.

Consequence: Every total, sound, injective presentation is isomorphic to EndoCase. No structurally distinct rival presentation survives.

Law 1.19–1.20: Orientation and Automorphism Presentation Uniqueness

The same uniqueness principle extends from endomorphisms to orientations and to automorphisms. The classification data are different in each case, but the constraint structure—total, sound, injective—is identical, and the round-trip witness is constructed by the same recipe.

Constraint: An orientation presentation must classify every DistinctionEquiv; an automorphism presentation must classify every Aut. Both must be total, sound, and injective with respect to pointwise equality of carrier maps.

Construction: The auxiliaries below supply the canonical classifier-as-function (orientationCase-classify, autCase-classify) and the canonical interpreter-as-equiv (orientationEquivInterpret, autEquivInterpret, with idEquiv and dualEquiv as their values). Their soundness lemmas close the round-trip equations on which the two presentation-uniqueness theorems depend.

Consequence: Every orientation presentation is forced isomorphic to OrientationCase; every automorphism presentation is forced isomorphic to AutCase. No structurally distinct rival survives in either setting.

The primitive distinction is stable. Equality, negation, decidability, witness structure, and the four endomorphism cases exist as machine-checked constraints on a two-element carrier. The base classification is locked.

But a classification that is not itself classified leaves a residue outside the filter. The next pressure is therefore unavoidable: the classifier must become an object inside the argument, and the argument must climb.

A number to remember. Four endomorphism cases have survived elimination. This number was not chosen—it fell out of the exhaustive analysis of a two-element carrier. It will reappear. When the argument finally converges on a graph, that graph will have exactly four vertices, and the combinatorial invariants of that graph—edge count, Euler characteristic, spectral decomposition—will produce specific integers. Once K_4 is forced, this four is promoted to an $\mathrm{Aut}(K_4)$-invariant by V-rigidity in the full ledger record theorem-autk4-full-ledger—a quantity invariant under the full automorphism chain, and therefore a necessary observable. The reader who notices the number four here and remembers it through the next hundred pages will recognize it again in a less abstract setting.

Part II

Drift and Reachability

Part I sealed the base and drew the first mark. A distinction appeared. Its carrier admitted exactly four endomorphisms. Those four maps were mutually distinct, exhaustive, and could not be collapsed further. The four reappears later as the vertex count of a specific graph; which graph structure that count is forced to carry is a separate derivation, executed in Part IV when the spectral and matching constraints converge.

But the classification itself is now a new mathematical object. The type EndoCase, the classifier function, the mutual distinctness proofs—none of these lived in the original carrier. They live one level above it. And that new object is not yet classified. Stopping here would leave an unclassified residue in the ontology, which is precisely the kind of residual freedom the filter is designed to eliminate.

Every act of classification produces a new unclassified object: the classification record itself. This is not a failure of the method—it is a structural property of any system that takes classification seriously. The minimal response is not to stop but to classify again, one level higher, each time inheriting the exact structure of the level below.

The result is a canonical tower. Agda's universe hierarchy is the meta-theoretic mechanism in which that ascent is recorded; equivalent stratifications (induction-recursion, Tarski-style universes, explicit reflection) would carry the same content. What is forced is the ascent itself, not the choice of mechanism that records it. The reachability proofs in this part are the formal record of that ascent: which levels are accessible from which, and by what minimal paths.

The specificity begins here. What emerges is not "a tower of some height" but a tower whose structure determines its successor and whose reachability relation admits no cycles. This rigidity is what later forces the survivor to be a single named graph rather than a family of candidates—and what later forces the arithmetic built on that graph to be similarly locked. The eliminative method, applied to its own infrastructure, leaves no room for choice.

Chapter 6

Drift

The new classification lives at a higher universe level, because it quantifies over the objects of the previous level. This is drift: the lift from one level to the next, carrying the old distinction into a lifted carrier that can accommodate the expanded ontology. The lift will be exhibited as universal in Chapter 8 and as the initial object of an explicit category of boundary-preserving lifts in Law 8; the word "canonical" is reserved for that point.

The drift step is not an invented construction. The structural demand is precise: every classification must itself be classifiable, and the type-theoretic hierarchy of universe levels is the unique mechanism that makes this possible without circularity.

 ... | inj₂ x≡r = inj₂ (cong lift x≡r)
```

Law 2.1: No Classification May Remain Unclassified

This is the law of closure. If a classification exists in the system, it must be classifiable—otherwise it sits outside the filter, untouched by elimination, a free parameter. The drift step provides the necessary embedding: the old carrier lifts into the new one, and the boundary witnesses lift with it.

```
-- § Law 2.1: No classification may remain unclassified.
law2-1-drift : {ℓ : Level} → (d : Distinctionℓ ℓ) → DriftStep d
law2-1-drift = drift

-- § Extract the next-level distinction from a drift step.
drift-next : {ℓ : Level} → (d : Distinctionℓ ℓ) → Distinctionℓ (lsuc ℓ)

drift-embed d = embed (drift d)

-- § Drift-embedded elements satisfy coverage.
drift-embed-cover : {ℓ : Level} → (d : Distinctionℓ ℓ) → (x : S d)
 → (drift-embed d x ≡ ℓ₀ (drift-next d)) ⊎ (drift-embed d x ≡ r₀ (drift-next d))
drift-embed-cover d x = cover (drift-next d) (drift-embed d x)
```

Drift is established: it lifts any distinction one universe level higher, preserving the boundary and coverage structure verbatim. The question that remains is whether this lift is safe—whether it distorts the carrier it inherits.

Chapter 7

Non-Collapse of Drift

Drift lifts the carrier to a higher universe level via lift. The critical question: does this lifting identify elements that were previously distinct? If it did, the boundary structure of the old distinction would collapse—ℓ and r might become equal in the lifted carrier. But lift is injective (its inverse lower is a witness), so the old separation survives verbatim. Drift expands the universe without folding the carrier.

Law 3.1: Drift Does Not Fold The Prior Carrier

The proof is immediate: lift has an inverse (lower), so any equation between lifted images reflects back to the originals. Boundary distinctness survives as a corollary—if ℓ_0 and r_0 could become equal after embedding, they would already be equal before it.

```
-- § Law 3.1: Drift does not fold the prior carrier.
law3-1-embed-injective :
 {ℓ : Level} (d : Distinction ℓ ℓ) → {x y : S d} →
 drift-embed d x ≡ drift-embed d y → x ≡ y
law3-1-embed-injective d = lift-injective

-- § Drift preserves boundary distinctness.
drift-embed-ℓ₀≠r₀ :
 {ℓ : Level} (d : Distinction ℓ ℓ) →
 drift-embed d (ℓ₀ d) ≠ drift-embed d (r₀ d)
drift-embed-ℓ₀≠r₀ d eq = ℓ₀≠r₀ d (law3-1-embed-injective d eq)
```

The lift is injective and the boundary separation survives. Drift expands the universe without folding the carrier. The next question is whether drift is unique among lifts that preserve this structure.

Chapter 8

Cross-Stage Comparison

Drift produces the simplest possible lift: lift wraps each element, and the boundary witnesses are preserved by refl. But there might be other ways to embed a distinction into a higher level—other choices of target carrier and embedding map that also preserve the boundary structure. The question is whether drift is in any way special among these alternatives.

It is. Drift is *universal*: for any boundary-preserving lift, there exists a unique mediating map from the drift carrier to the alternative carrier that makes the diagram commute. The categorical content of this universality—that drift is the initial object in a genuine category whose objects are boundary-preserving lifts and whose morphisms are mediator triangles—is established once the category structure is in scope (Law 8). The present chapter establishes the mediator and its uniqueness; the next subsection supplies the identity, composition, and coherence laws that turn "initial object" from a slogan into a theorem.

Law 4.1: Drift Is Universal Among Boundary-Preserving Lifts

Universality is witnessed constructively: the mediator sends each lifted element back through lower and re-embeds via the alternative lift. Commutativity is definitional (refl), and uniqueness follows because both distinctions have exactly two elements—any function agreeing on both boundary values agrees everywhere.

```

law4-2-factor-unique = drift-factor-unique
```

Law 4.3: The Category of Boundary-Preserving Lifts

Universality up to factorisation is meaningful only inside a category. Without identity, composition, and the identity/associativity equations, "initial object" is a slogan rather than a theorem. The structure on LiftMorph below supplies the missing infrastructure: the identity morphism preserves boundaries by refl, composition pastes the commuting triangles together, and the three coherence equations hold definitionally. With this in place, the universal-property statement of Law 4.1 becomes the categorical statement that drift is the initial object in the category $\mathcal{L}_d$ of boundary-preserving lifts of d.

Constraint: A factorisation theorem outside a category is incomplete. Identity and composition must exist, and they must satisfy the equations that make "the unique mediator" well-defined as a morphism between objects.

Construction: The identity morphism is the identity function on the carrier; composition is function composition with a one-line proof that boundary-preservation propagates. The two unit laws and associativity reduce to refl on every input, so they are witnessed by the trivial pointwise equality on every element of the source carrier.

Consequence: The structure $\mathcal{L}_d = (\text{LiftedBP } d,\ \text{LiftMorph } d,\ \text{liftId},\ \text{liftComp})$ is a category; driftLiftedBP is its initial object, with drift-factor supplying the unique morphism to any other object (Law 4.1, Law 4.2).

```

Drift is universal: every boundary-preserving lift factors through it, and the factorization is unique. No alternative lift can bypass the drift step. The tower is therefore canonical—the depth of the reachability chain is the next question.

Chapter 9

Drift Reachability

Drift does not stop. There is no final universe level where the process terminates—every distinction at level ℓ drifts to level $\ell + 1$, and that lifted distinction drifts again. The reachability relation captures this infinite progression: state t is reachable from state s if there is a finite chain of drift steps connecting them. Strict reachability (Reach^+) requires at least one step; reflexive-transitive reachability (Reach) allows zero.

The key structural facts follow from the uniqueness of successors. Since each drift state has exactly one successor, there is no branching—the reachability order is a total preorder on any connected chain. Every finite chain extends by one more step. And the chain never loops back (as the next chapter proves).

 {s t : DriftState} → (p : Reach s t) → P s t p
law5-7-Reach-elim = Reach-elim
```

Reachability is explicit: every finite chain extends, strict successors are comparable, and the eliminator is forced. The chain stretches forward without bound. The last structural hazard is circularity—whether the chain could loop back and collapse the hierarchy it has built.

Chapter 10

Drift Acyclicity

A tower that never stops climbing is not safe merely because it grows. If a chain of drift steps could fold back on itself—returning to a state already visited—then the hierarchy would collapse into a finite loop, and the infinite ascent would be an illusion. Without acyclicity, the hierarchy would apply only to cycles, not to a genuine progression. The elimination strategy demands that the tower be rigid: once a state is left behind, it is left behind permanently.

The drift sequence is infinite—but is it linear? Could a chain of drift steps loop back to a previous state? If it could, then a distinction at some level ℓ would be identified with a distinction at a higher level $\ell + k$, collapsing the universe hierarchy. This is structurally impossible: universe levels in Agda are well-ordered, and lsuc is strictly increasing. But the formal system must witness this impossibility explicitly. The acyclicity constraint states that no drift state is strictly reachable from itself, and the consequences—irreflexivity, asymmetry, and absence of fixed points—follow immediately.

```
-- § Acyclicity constraint on drift.
record DriftAcyclic : Setω where
 field
  no-cycle : (s : DriftState) → (s ≺ s) → ⊥

```

Law 6.0: Drift Has No Cycles

Acyclicity is recorded as a constraint: any cycle $s \prec s$ leads to absurdity. The implementation extracts the contradiction directly from the DriftAcyclic record.

```
-- § Law 6.0: Drift has no cycles.
law6-0-no-cycle : DriftAcyclic → (s : DriftState) → (s ≺ s) → ⊥
law6-0-no-cycle ac s p = no-cycle ac s p
```

Law 6.1: Strict Reachability Is Irreflexive

Irreflexivity is the immediate instance of acyclicity: $s \prec s$ is itself a cycle of length one.

```
-- § Law 6.1: Strict reachability is irreflexive.
law6-1-irreflexive : DriftAcyclic → (s : DriftState) → (s ≺ s) → ⊥
law6-1-irreflexive ac s = no-cycle ac s
```

Law 6.2: Strict Reachability Is Asymmetric

If both $s \prec t$ and $t \prec s$ held, transitivity would produce the cycle $s \prec s$, contradicting acyclicity.

```
-- § Law 6.2: Strict reachability is asymmetric.
law6-2-asymmetric :
 DriftAcyclic → {s t : DriftState} →
 (s ≺ t) → (t ≺ s) → ⊥
law6-2-asymmetric ac p q = no-cycle ac _ (≺-trans p q)
```

Law 6.3: Drift-Step Has No Fixed Point

If stepState s equalled s, then the single-step witness one could be transported into a self-loop $s \prec s$, contradicting acyclicity.

```
-- § Law 6.3: Drift-step has no fixed point.
law6-3-no-fixpoint-stepState : DriftAcyclic → (s : DriftState) → stepState s ≡ω s → ⊥
law6-3-no-fixpoint-stepState ac s eq =
 no-cycle ac s (substω (λ u → Reach⁺ s u) eq one)
```

Law 6.4: Drift Is a Strict Total Order

The pieces are now in place. Strict reachability $\prec$ is transitive (Law 5.3), irreflexive under acyclicity (Law 6.1), asymmetric under acyclicity (Law 6.2), and comparable along a common ancestor (Law 5.1). These four properties together constitute a strict total order on every drift chain emanating from a fixed source. The following record bundles them as a single citable theorem; no new proof work is required to assemble it.

The scope of the comparability field is exact, and the prose must respect it. DriftState is universe-polymorphic: two states whose underlying carriers live at unrelated levels share no canonical comparison. Comparability is therefore stated relative to a common predecessor and not as a global trichotomy on the entire type. This is not a weakness of the proof but a property of the object: drift acts on a chosen carrier and propagates from there; a chain is the natural domain of the order.

Constraint: A chain without a total order could branch or merge, allowing two incomparable development paths from the same root. Rigidity demands that any two states with a common predecessor stand in a definite before-or-after relation.

Construction: The four required fields—transitivity, irreflexivity, asymmetry, comparability-from-a-common-source—are inhabited by Laws 5.3, 6.1, 6.2, 5.1 respectively. The bundle exists; reach proofs themselves are unique (Law 6.5), so the transitivity field is forced pointwise.

Consequence: On every chain rooted at a fixed source, the strict order on drift states is uniquely determined as a term-level object. The orbit-level refinement that sharpens this into

an explicit trichotomy on ω is established once the indexed ledger has been introduced (Law 6.6 and the orbit total-order theorem that follows).

```
– § Strict total order on drift states
record DriftStrictTotalOrder (ac : DriftAcyclic) : Setω where
 field
  sto-trans       : {s t u : DriftState} → (s ≺ t) → (t ≺ u) → (s ≺ u)
  sto-irrefl      : (s : DriftState) → (s ≺ s) → ⊥
  sto-asym        : {s t : DriftState} → (s ≺ t) → (t ≺ s) → ⊥
  sto-comparable : {s t₁ t₂ : DriftState} →
                    s ≺ t₁ → s ≺ t₂ → (Reach t₁ t₂) ⊎ω (Reach t₂ t₁)

– § Theorem: drift is a strict total order
theorem-drift-strict-total-order :
 (ac : DriftAcyclic) → DriftStrictTotalOrder ac
theorem-drift-strict-total-order ac = record
 { sto-trans = law5-3-≺-trans
 ; sto-irrefl  = law6-1-irreflexive ac
 ; sto-asym = law6-2-asymmetric ac
 ; sto-comparable = law5-1-comparable
 }
```

The climb through the universe hierarchy is explicit. Drift does not terminate, reachability records the ascent, and acyclicity prevents the hierarchy from folding back onto itself. The argument carries vertical structure without losing rigidity.

But that is still not enough. If the four surviving cases depended on the source and target being the same carrier, then the classification would be parochial rather than structural. The next task is therefore to remove that loophole.

Part III

Heteromorphisms and Presentation

Part II built a tower: every self-classification step carries the structure one level higher, and the reachability facts between those levels form a well-founded order. The drift hierarchy is not circular, and no level collapses back into a previous one. What the tower established, though, is a picture of maps within a single carrier—endomorphisms of the distinction. The question now presses from a different direction. Two carriers exist; maps between them should face the same combinatorial constraints as maps within one.

The classification established in Part I was confined to maps from a distinction carrier to itself. The question now is whether relaxing that restriction changes anything. It does not—the same two-boundary combinatorics governs every map, regardless of whether domain and codomain coincide.

This consistency matters—but it matters more than it might first appear. If maps *between* carriers are just as constrained as maps *within* a single carrier, then the four-case structure is not an artifact of the self-mapping assumption. It is a property of the two-class distinction itself, holding regardless of which carrier provides the domain and which the codomain. The confirmation shuts another door: there is no freedom in the map type, and there is no freedom in how the map type is represented. The presentation theorems that follow press this further: every reachability fact between levels reduces to a finite canonical record, and every canonical record to its minimal representative.

The singleton character of the survivor begins to crystallize here. If the presentation admitted more than one canonical form, the chain would fork and the later invariant record could not be unique. That the canonical form is itself unique—not merely existent—is what transmits the eliminative pressure forward: from infrastructure through the tower, through the cross-carrier maps, toward the single graph and the forced arithmetic that graph demands.

Chapter 11

Heteromorphisms

A map $f : S_{d_1} \to S_{d_2}$ between two distinct distinction carriers is governed by the same two-boundary constraint as the endomorphisms of Part I: its behavior is determined by its values on the two source classes, each forced into one of the two target classes. The 2×2 combinatorics is identical; injectivity, soundness, and uniqueness carry over without modification.

This chapter lifts the entire classification machinery—interpretation, classification, soundness, injectivity, uniqueness—from the endomorphism setting to the heteromorphism setting. The proofs are structurally identical; only the types change. The four canonical maps between two distinctions are: constant-left, constant-right, the boundary-preserving map (LR), and the boundary-swapping map (RL).

Constraint: Coverage acts on every distinction carrier independently. Source-side coverage forces the input into one of two boundary classes; target-side boundary distinctness forces each output into one of two boundary witnesses. Together they re-impose the same 2×2 combinatorics as in the endomorphism case, regardless of whether source and target coincide.

Elimination: A fifth heteromorphism class would demand either a third source class (forbidden by source coverage) or a third target value (forbidden by $\ell_{d_2} \neq r_{d_2}$). A third class would demand collapsing two of the four—identifying two distinct interpretations on the boundary, again forbidden by target boundary distinctness. The four canonical maps therefore exhaust the type, and the heteromorphism case adds no new structure beyond what the endomorphism case already established.

Consequence: The four-case classification is structural, not parochial: it survives the relaxation from self-mapping to cross-carrier mapping unchanged. Every law of the endomorphism classification re-emerges in the inter-distinction setting, and the bijection record $\mathrm{MapBijection}$ below packages it as a single citable witness.

Step 1: Map type and canonical inter-distinction maps. The map type, pointwise equivalence, and four canonical maps between two distinction-carriers mirror the endomorphism case. The two mixed maps LR and RL use source-side coverage to assign the appropriate target boundary witness.

```
-- § K₄ maps between two distinctions.

RL-r : RL (r d₁) ≡ ℓ d₂
RL-r with cover d₁ (r d₁)
... | inj₁ r≡ℓ = ⊥-elim ((ℓ≠r d₁) (sym r≡ℓ))
... | inj₂ _ = refl
```

Step 2: Interpretation and classification of inter-distinction maps. Each EndoCase label interprets as one of the four canonical maps, and every concrete map is classified by its boundary outputs.

```
-- § Interpret an EndoCase as a map between distinctions.
interpret : EndoCase → Map
```

```
interpret case-constL = constL
interpret case-constR = constR
interpret case-id     = LR
interpret case-dual = RL

-- § Classify a map by its boundary behavior.
classify : Map → EndoCase
classify f with cover d₂ (f (ℓ d₁)) | cover d₂ (f (r d₁))
... | inj₁ _ | inj₁ _ = case-constL
... | inj₂ _ | inj₂ _ = case-constR
... | inj₁ _ | inj₂ _ = case-id
... | inj₂ _ | inj₁ _ = case-dual
```

Step 3: Soundness of inter-distinction classification. Classification followed by interpretation recovers the original map at both boundary witnesses.

```
-- § Soundness at ℓ.
sound-at-ℓ : (f : Map) → interpret (classify f) (ℓ d₁) ≡ f (ℓ d₁)
sound-at-ℓ f with cover d₂ (f (ℓ d₁)) | cover d₂ (f (r d₁))
... | inj₁ fl≡ℓ | inj₁ _ = sym fl≡ℓ
... | inj₂ fl≡r | inj₂ _ = sym fl≡r
... | inj₁ fl≡ℓ | inj₂ _ = trans LR-ℓ (sym fl≡ℓ)
... | inj₂ fl≡r | inj₁ _ = trans RL-ℓ (sym fl≡r)

-- § Soundness at r.
sound-at-r : (f : Map) → interpret (classify f) (r d₁) ≡ f (r d₁)
sound-at-r f with cover d₂ (f (ℓ d₁)) | cover d₂ (f (r d₁))
... | inj₁ _ | inj₁ fr≡ℓ = sym fr≡ℓ
... | inj₂ _ | inj₂ fr≡r = sym fr≡r
... | inj₁ _ | inj₂ fr≡r = trans LR-r (sym fr≡r)
... | inj₂ _ | inj₁ fr≡ℓ = trans RL-r (sym fr≡ℓ)

-- § Classification is sound: the interpreted classify agrees pointwise with f.
classify-sound : (f : Map) → interpret (classify f) ≐ f
classify-sound f x = Distinction-elim d₁ (sound-at-ℓ f) (sound-at-r f) x

-- § Maps are determined by their boundary values.
map-determined :
 (f g : Map) →
 f (ℓ d₁) ≡ g (ℓ d₁) →
 f (r d₁) ≡ g (r d₁) →
 f ≐ g
map-determined f g eqℓ eqr x = Distinction-elim d₁ eqℓ eqr x

-- § Absurdity helpers.
absurd-ℓr : {A : Set} → (ℓ d₂ ≡ r d₂) → A
absurd-ℓr e = ⊥-elim ((ℓ≠r d₂) e)

absurd-rℓ : {A : Set} → (r d₂ ≡ ℓ d₂) → A
absurd-rℓ e = ⊥-elim ((ℓ≠r d₂) (sym e))
```

Step 4: Injectivity and uniqueness. Interpretation is injective: the 4×4 case matrix either produces refl or derives absurdity from $\ell \neq r$. Together with soundness, this forces classification uniqueness.

```
interpret-injective :
 (c c' : EndoCase) →
```

```
 interpret c ≐ interpret c' →
 c ≡ c'
interpret-injective case-constL case-constL _ = refl
interpret-injective case-constL case-constR p = absurd-ℓr (p (ℓ d₁))

 f ≐ g
law7-1-map-determined d₁ d₂ = K₄Map.map-determined d₁ d₂
```

Law 7.2: K_4 Classification Produces A Witness For Any Map

Every map between two distinctions receives a classification witness: a case label paired with a proof that the labeled canonical map agrees with the given map at every point. The proof strategy is identical to the endomorphism case—inspect the two boundary outputs, match the pattern, verify pointwise.

```
– § Law 7.2: K₄ classification produces a witness for any map.
law7-2-k4map-classification-sound :
 (d₁ d₂ : Distinction) →
 (f : S d₁ → S d₂) →
 Σ EndoCase (λ c → K₄Map.interpret d₁ d₂ c ≐ f)
law7-2-k4map-classification-sound = k4map-classification-sound
```

Law 7.3: K_4 Witness For Maps Is Unique

Two distinct case labels cannot interpret to the same map. If they did, their boundary outputs would simultaneously agree, which forces boundary witnesses in the codomain to be equal—contradicting $\ell \neq r$.

```
– § Law 7.3: K₄ witness for maps is unique.
law7-3-k4map-classification-unique :
```

```
(d₁ d₂ : Distinction) →
(f : S d₁ → S d₂) →

Law 7.5: Map Classification Is a Bijection

The same closure that completed the endomorphism classification (Law 1.8) closes the inter-distinction case. The classifier is a left-inverse of interpretation: classify any interpreted label, recover the same label exactly. Combined with soundness (Law 7.2), uniqueness (Law 7.3), and boundary determination (Law 7.1), this turns the four cases into a strict bijection between EndoCase and the quotient $Map/\mathring{=}$.

Constraint: A heteromorphism classification that holds only one direction would leave room for two distinct labels to denote the same equivalence class of inter-distinction maps. The two-way round-trip forecloses this in the cross-carrier setting exactly as it did in the self-mapping setting.

Construction: Uniqueness applied to the trivial witness $interpret\, c \mathring{=} interpret\, c$ forces $classify\,(interpret\, c) \equiv c$. The bijection record MapBijection bundles the four required laws into a single citable witness.

Consequence: The four-case structure is the cardinality of the inter-distinction map quotient. There is no room for a fifth heteromorphism class, and no room for two of the four to collapse into one—neither within a single carrier nor between distinct carriers.

```
– § Law 7.5: classify ∘ interpret = id at the case-label level for inter-distinction maps.
law7-5-k4map-classify-interpret :
 (d₁ d₂ : Distinction) →
 (c : EndoCase) →
 K₄Map.classify d₁ d₂ (K₄Map.interpret d₁ d₂ c) ≡ c
law7-5-k4map-classify-interpret d₁ d₂ = K₄Map.classify-interpret d₁ d₂
```

The four-case classification extends from endomorphisms to arbitrary maps between distinct carriers. The same four cases survive, and the same uniqueness holds. The classification is structural, not an artefact of the self-mapping assumption.

Chapter 12

Indexed Ledger

The drift sequence produces an infinite chain of states, each at a higher universe level. Tracking position in this chain requires an index. The natural numbers provide the canonical index: a drift state paired with a tick count. The tick increases by exactly one at each step, and this strict increase is the key to proving acyclicity without appealing to properties of universe levels directly.

The indexed ledger is not additional structure—it is a *presentation* of the drift chain that makes its combinatorial properties (finiteness of chains, monotonicity of tick) directly accessible to the type checker.

law8-1-no-cycleℕ s p = suc≤-impossible (tick s) (law8-0-tick-increases p)
```

Law 6.6 (deferred): Tick Presents Every Drift Orbit As ω

The strict-order assertion of Law 6.4 gains its ordinal content here. Drift acts on a chosen carrier and propagates from there; the orbit it generates over a fixed base b is a chain, and that chain is what tick presents as ω. Once the indexed ledger is in scope, the orbit map $n \mapsto \langle n, \mathit{step}^n(b)\rangle$ sends every natural number to an indexed drift state, the strict ordering $\prec_{\mathbb{N}}$ pulls back to the standard $<$ on $\mathbb{N}$ via Law 8.0, and conversely every positive index gap yields a strict reach proof. Tick is therefore not merely a counter; on each orbit it is an order-isomorphism with ω.

The scope is exact. The claim is not that all of $\mathrm{DriftState}\mathbb{N}$ forms a single ω-chain—universe-polymorphism forbids comparing states that share no carrier. The claim is that on every orbit generated from a fixed base, no other ordinal type is admissible, because the two-way correspondence with $\mathbb{N}$ leaves no room for one.

Constraint: An assertion that a drift orbit has ordinal type ω must be backed by an explicit order-preserving correspondence with $\mathbb{N}$ in both directions; without the converse, the claim collapses into mere monotonicity.

Construction: The orbit map $n \mapsto \langle n, \mathit{step}^n(b)\rangle$ supplies the bijection on carriers, definitional reduction supplies the tick-readout and the step compatibility, the iteration of $\mathrm{Reach}^+\mathbb{N}$-extend supplies the forward direction (positive index gap implies strict reach), and Law 8.0 supplies the backward direction (strict reach implies positive index gap). The record $\mathrm{TickIso}\omega$ bundles all six fields into a single citable witness parameterised by the chosen base.

Consequence: Any other ordering on the orbit that respects $\prec_{\mathbb{N}}$ must agree with the $\mathbb{N}$-ordering pulled back along tick. The ordinal type of every drift orbit is forced to be ω, and the orbit-level trichotomy theorem that follows turns this isomorphism into an explicit case split on $\mathbb{N}$.

Law 6.4 Refined: Orbit Trichotomy

The strict-order assertion of Law 6.4 was scoped to chains rooted at a common predecessor. The orbit machinery sharpens this to an explicit case split: any two natural-number indices n, m satisfy exactly one of the three relations $n < m$, $n = m$, $m < n$, and the orbit map transports each case to the corresponding orbit-state relation $\prec_{\mathbb{N}}$, $\equiv_{\omega}$, or $\succ_{\mathbb{N}}$. Trichotomy on ω is not assumed; it is forged from the standard ordering on $\mathbb{N}$ and the two-way correspondence reachSound / reachComplete of TickIsoω.

Constraint: A claim of strict total order on the orbit must, when translated into a constructive setting, exhibit the trichotomy as a decidable case distinction; abstract comparability without an algorithm is constructively empty.

Construction: Trichotomy on $\mathbb{N}$ is forged by induction on both arguments. The orbit map then transports each branch into a Set_{ω}-level witness: the strict cases use orbit-reach-sound (which is itself derived from the forward direction of TickIsoω); the equality case uses index-congruence on *orbitState*.

Consequence: The orbit over any chosen base is a constructively decidable strict total order. Combined with Law 6.6, this leaves no room for a non-ω ordinal type on any drift orbit, and no room for two states on the same orbit to be incomparable.

```

```

The indexed ledger now carries a monotonically increasing tick, acyclicity follows from the impossibility of a successor being less than or equal to itself, and the ordinal type of every drift orbit is fixed as ω. The ledger is a faithful presentation of the drift chain—no loop is concealed, and the linear order on each orbit is not abstract but explicit through tick.

Chapter 13

Presentation of Reachability

Every formal system carries bookkeeping. Indices, counters, witness labels—all the machinery that makes the proof checkable also makes it heavier than the theorem it proves. The indexed ledger from the previous chapter is bookkeeping of exactly this kind: it adds a tick count to each drift state, and the tick is genuine extra data—the function $\langle n, b\rangle \mapsto n$ separates indexed states that share the same base. Any uniformity claim must therefore restrict to observables that ignore this added data. The class of such observables is precisely the admissible ones; on that class, the tick collapses provably.

This chapter makes the collapse precise. It establishes a forget/lift adjunction between the indexed and base reachability relations, derives the notion of admissible observable (a function that respects the base projection), shows that every admissible observable factors uniquely through the forgetful map, and—at the close—exhibits the tick itself as a non-admissible observable. The negative result locates the boundary of the collapse: bookkeeping that ignores base-equality is annihilated; bookkeeping that records it is exposed as content rather than scaffold.

Laws 9.0–9.2: Forget/Lift Round-Trip

The forget map strips the index, recovering the original level-polymorphic reachability proof. The lift map attaches an index. The round-trip law states that forgetting a lifted proof returns the original—the index carries no information that survives projection.

The four-case classification survives the passage from endomorphisms to maps between distinct carriers, and the resulting reachability data reduces to canonical presentations. The argument controls not only what structures exist, but how their witnesses may be normalized. The number four reappears at every stage—not because the argument is steered toward it, but because no other cardinality survives the constraints. The graph that four mutually distinct elements demand is the complete graph K_4, and its emergence is imminent.

Normalization alone does not yet isolate the invariant content. The next pressure is to separate structural observables from bookkeeping residue and force the presentation to collapse to its irreducible core. When it does, the surviving object will not be an abstract category-theoretic residue. It will be a concrete graph with four vertices and six edges—a tetrahedron—and its spectral invariants will carry numerical weight.

Part IV

Observables and Fixpoint

Parts I through III established that only four cases survive at every level and in every map direction. The tower rises without branching; the map space closes without remainder. But a new pressure arises. Two proof witnesses that trace the same logical path may differ entirely in their internal bookkeeping—the tick indices, the staging records, the intermediate certificates. A measurement that depends on such bookkeeping is not an observable of the path; it is a reading of the ledger that recorded it.

The question this pressure forces is precise: which observables on reachability proofs survive the replacement of any proof by any other proof of the same proposition? An observable that disagrees with itself when bookkeeping changes is not measuring the path—it is measuring the notation. The admissible observables are those that survive unchanged. Everything else is stripped away. The filter is the same one that ran through the preceding parts: test every candidate, eliminate anything that depends on a choice, keep only what survives.

This part identifies which observables on reachability proofs have that property: the admissible ones, determined solely by the underlying path rather than the bookkeeping that traced it. The answer converges to a fixpoint. Every admissible observable factors through a base computation that discards staging, tick-indexing, and witness detail, retaining only the irreducible logical content. That content is exactly K_4. This is not a construction arriving at it from outside; it is the proof that K_4 is what all the preceding elimination steps were closing toward. The K_4 graph presentation at the close of this part is that content—the single minimal certificate of everything the four preceding parts established.

The poverty-to-richness gap is now fully visible. The derivation began with nothing—no axioms, no structure, no numbers—and has arrived at a named, rigid object whose combinatorial invariants are determined. The arithmetic required to evaluate those invariants must be forced by the same discipline: if the naturals, integers, rationals, or reals were imported rather than derived, the derivation's claim to self-sufficiency would collapse. That arithmetic is the work of Part V. The invariant record it produces is the work of Part VI—where the record is proved to be a singleton, the measurement kernel establishes an independent route to the root, and the final theorem closes the loop from the invariant record back to the distinction that started the chain.

Chapter 14

Admissible Reach Observables

The question driving this chapter is deceptively simple: does the path between two drift states depend on how it was recorded? If a measurement on the journey changes when the indexing scheme changes, then the index is part of the content and cannot be stripped. If every measurement remains invariant, then the index is pure scaffolding—necessary for construction, irrelevant to the result. The answer determines whether the tower of drift states carries genuine infinite complexity or whether it is, beneath the bookkeeping, a finite record.

The previous chapter stripped the tick index from state observables. Strict reachability proofs carry exactly the same redundancy: their indexed form $\mathrm{Reach}^{+}\mathbb{N}$ records which tick-stamped ledger entry witnessed each step, but the underlying path through drift space—the base proof Reach^{+}—is already determined by the sequence of states visited. Any observable that depends on the indexed proof but commutes with the forgetful map is therefore forced to factor through the base proof alone. This chapter lifts the entire admissibility apparatus to reach proofs and confirms that the tick layer collapses here as well: every admissible reach observable reduces to a function of the tick-free path.

```

Laws 10.4–10.6: Reach Observable Infrastructure

With factoring and transitivity compatibility established, the remaining infrastructure falls into place. Each admissible reach observable carries both an indexed observer and a base mediator—but the base mediator already determines the indexed one. Packing a base reach observable into admissible form and then reading off the base component recovers the original: the round-trip is trivially the identity. Uniqueness of the indexed component given a base mediator then follows from the factorization laws above.

Laws 10.7–10.11: Reach Observational Normal Forms

Two admissible reach observables that agree on every indexed proof are observationally indistinguishable—they produce the same output on every input, so no context can separate them. The canonical normal form packs the base mediator back into admissible form, discarding whatever indexed overhead the original carried. Applying this normalization twice changes nothing: the canonical form is already base-packed, so the second pass is a no-op up to observation. The resulting iso between admissible reach observables and base reach observables is the definitive collapse: the tick index contributes no observable content to reachability, exactly as it contributed none to state.

Chapter 15

Ranking Principle

Acyclicity stated as a constraint tells the formal system what to rule out, not why the exclusion holds. A constructive witness is stronger: rather than forbidding cycles, it makes them impossible by construction. The ranking principle provides that witness.

Inside the $\mathrm{DriftAcyclic}$ record, the acyclicity field blocks any state from reaching itself via a non-empty path. A rank function makes this constraint inhabitable. If every drift step strictly increases a natural-number rank, then any non-empty cycle $s \prec^{+} s$ would force $\mathrm{suc}\ (\mathrm{rank}\ s) \leq \mathrm{rank}\ s$, which is impossible in $\mathbb{N}$. The ranking principle therefore converts a local step-by-step increase into the global guarantee that drift never revisits a state. If every drift step strictly increases a natural-number rank, then any non-empty cycle $s \prec^{+} s$ would force $\mathrm{suc}\ (\mathrm{rank}\ s) \leq \mathrm{rank}\ s$, which is impossible in $\mathbb{N}$. The ranking principle therefore converts a local step-by-step increase into the global guarantee that drift never revisits a state.

```
-- § Ranking record.
record DriftRank : Setω where
 field
  rank : DriftState → ℕ
  rank-step : (s : DriftState) → suc (rank s) ≤ rank (stepState s)

open DriftRank public
```

Law 11.0: Rank Is Monotone Along Reach^{+}

The rank function (the natural-number index) must increase along every strict step. This is forced by the definition of $\mathrm{stepState}_{\mathbb{N}}$, which increments the index by one.

```
-- § Law 11.0: Rank is monotone along Reach⁺.
law11-0-rank-mono : (r : DriftRank) → {s t : DriftState} → (s ≺ t) → rank r s ≤ rank r t
law11-0-rank-mono r {s} one =
 ≤-trans (≤-step (rank r s)) (rank-step r s)
law11-0-rank-mono r {s} (more p) =
 ≤-trans
  (≤-trans (≤-step (rank r s)) (rank-step r s))
  (law11-0-rank-mono r p)

-- § Strict monotonicity.
law11-0-rank-increases : (r : DriftRank) → {s t : DriftState} → (s ≺ t) → suc (rank r s) ≤ rank r t
```

```
law11-0-rank-increases r {s} one = rank-step r s
law11-0-rank-increases r {s} (more p) =
 ≤-trans (rank-step r s) (law11-0-rank-mono r p)
```

Law 11.1: Ranking Forces Acyclicity

With monotonicity in hand, the final step is immediate. A strict cycle $s \prec^{+} s$ forces $\mathrm{suc}\ (\mathrm{rank}\ s) \leq \mathrm{rank}\ s$—a successor that is no larger than the number it succeeds, which $\mathrm{suc}\leq\text{-impossible}$ refutes outright. Any drift system carrying a rank function is therefore acyclic by construction, not by fiat.

```
-- § Law 11.1: Ranking forces DriftAcyclic.
law11-1-ranked-acyclic : DriftRank → DriftAcyclic
law11-1-ranked-acyclic r =
 record
  { no-cycle =
    λ s p →
      suc≤-impossible (rank r s) (law11-0-rank-increases r p)
  }
```

Chapter 16

Presentation Fixpoint

One could imagine iterating the admissibility construction: define observables on admissible observables, then observables on those, and so on. But the hierarchy collapses at the first level. Any functional on admissible state observables that respects observational equality already factors through the base observable observe—it cannot detect the tick index even indirectly, because the canonical normal form has already erased it. The same argument applies to reach observables. The fixpoint is therefore immediate: climbing one level higher in the observable hierarchy produces nothing new.

Global Observable Elimination

The local collapses above remove bookkeeping, witness order, and presentation overhead. But that is not yet the final verdict. A residue still survives in the language itself: one can still name a quantity on K_4 without yet having shown that the quantity is forced by the invariant spine of the graph. If that step is left open, contingency re-enters through description. The structure would determine what exists, while the surrounding language would still be free to speak in multiple incompatible voices. Nature does not permit that split. Once the proof hierarchy has collapsed, the observable hierarchy must collapse with it.

Constraint: Every admissible observable on the surviving K_4 presentation must be insensitive not only to tick indices and witness detail, but to presentation choice itself. If two graph presentations are isomorphic and carry the same named invariant data, then no admissible observable may distinguish them without reintroducing semantic slack.

Elimination: Every admissible observable that fails to factor through the canonical invariant basis is eliminated: its sensitivity to presentation detail contradicts the constraint above. The global theorem is therefore an elimination principle for K_4 observables, collapsing the admissible sector to those that factor through the already forced basis. In the concrete K_4 specialization carried later in the manuscript, this collapse reduces the sector to exactly four canonical observable classes: boundary, spectral, complement, and edges. In schematic form,

$$\text{ObservableElim} : (\text{admissible } K_4\text{-observable}) \to (\text{canonical invariant basis} \to Y),$$

with commutation showing that evaluation on any admissible presentation is exactly evaluation on the extracted basis data.

Consequence: This closes the last gap between structural necessity and descriptive necessity. Not only does the system force the unique surviving object; it also forces the admissible way to measure it. The earlier laws already prove this collapse for indexed state observables, reach observables, and their first meta-level. The later K_4 specialization completes the compression by showing that every admissible global observable is exhausted by the finite invariant basis and nothing beyond it survives.

Figure 16.1 fixes this collapse schematically. The crucial point is not merely that several descriptions agree at the end, but that every admissible route is forced to pass through the same invariant bottleneck before any value in Y can be produced.

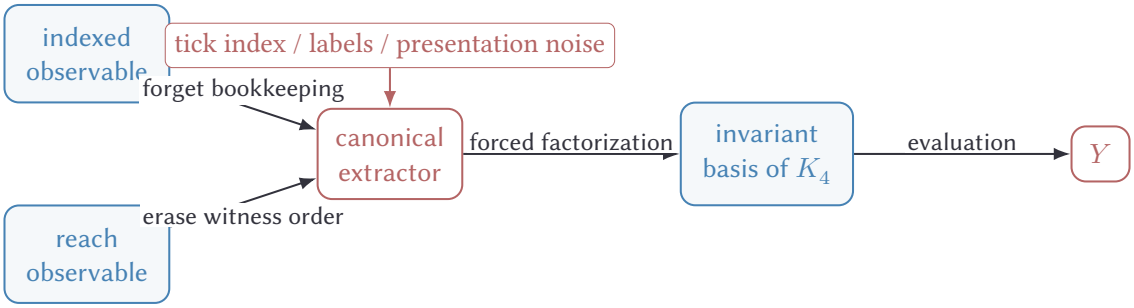

Figure 16.1: Observable fixpoint: every admissible observable is forced through the same K_4 invariant basis before it can produce a value.

Chapter 17

Graph Presentation

The derivation has climbed through a tower of distinctions, classified every map on the carrier, generalised the classification from endomorphisms to heteromorphisms, stripped away presentation overhead, collapsed the observable hierarchy to its fixpoint, and established that a unique canonical structure survives elimination. That structure is K_4: the complete graph on four vertices. Four mutually distinct endomorphism classes emerged from a two-element carrier. No fifth class survived. No three-class truncation was self-consistent. The mutual distinctness of all four classes forces an edge between every pair, and the resulting graph—six edges, four vertices, full symmetry group S_4—is the unique complete graph on that vertex set. The tetrahedron is not a model chosen from a catalogue. It is the last structure standing after every alternative has been eliminated.

The numerical invariants of this graph—vertex count, edge count, Euler characteristic, spectral decomposition—are assembled into the invariant ledger in the next chapter. Before that ledger can be read, the graph itself must be exhibited and its uniqueness up to isomorphism proven.

Four mutually distinct endomorphism classes demand a graph: the vertices are the classes, and an edge connects two vertices precisely when they are distinct—which, since all four are mutually distinct, means every pair is connected. This is the complete graph K_4. Any alternative presentation that re-labels the vertices through a bijection to EndoCase produces a graph isomorphic to this canonical one—the bijection transports edges faithfully, and distinctness is invariant under renaming. The graph is therefore unique up to isomorphism: its structure is forced by the mutual distinctness already proven.

 ; edge-irr = λ a loop → loop refl
 }
```

Law 13.1: Any K_4 Graph Presentation Collapses To The Canonical Graph Up To Iso

A presentation provides an alternative vertex type with a bijection to EndoCase. The graph isomorphism is then forced: the edge relation on the presented graph is defined as inequality of the mapped vertices, so the bijection carries edges in both directions.

Figure 17.1 makes the collapse visible. The left-hand graph may wear arbitrary vertex names, but the bijection to EndoCase strips that presentation freedom away and lands on the same complete four-vertex object. Nothing structural is transported except the renaming itself.

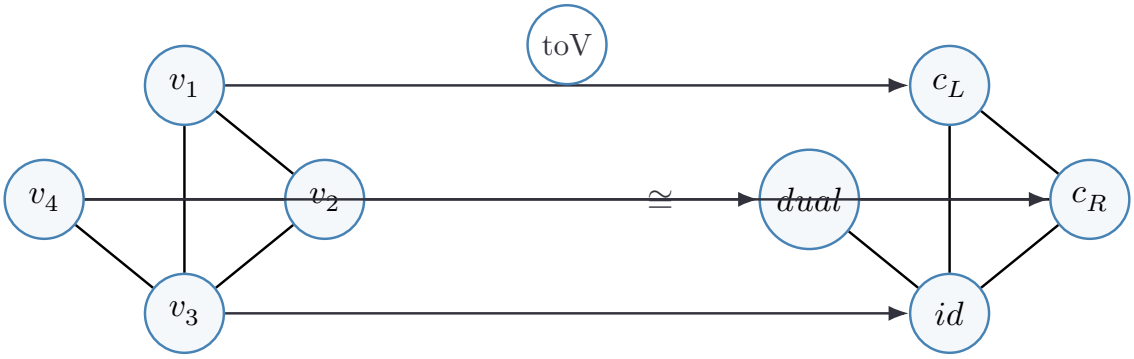

Figure 17.1: Graph presentation collapse: an arbitrary four-vertex presentation is forced, via bijection to EndoCase, onto the same canonical K_4.

```

 ; edge-to = λ {a} {b} e → e
 ; edge-from = λ {a} {b} e →
   transport≠ (sym (to-from p a)) (sym (to-from p b)) e
 }
```

Law 13.2: K_3 Cannot Host the Four Cases

The exhaustive four-case classification of Chapter 4 forced four mutually distinct endomorphism classes from a two-class carrier. The graph that records this distinctness must contain at least four vertices: each class needs its own vertex, and EndoCase-distinct forbids any two from collapsing into one. A three-vertex graph has too few seats. Pigeonhole forces two classes to share a vertex, contradicting their proven distinctness.

This is not a soft failure. It is the formal annihilation of the first plausible alternative to K_4. The triangle is the smallest graph that can carry edges between mutually distinct vertices at all—and yet it is exactly one vertex short of carrying the four classes. The verdict is constructive: the proof exhibits a contradiction term.

Constraint: The classification produces four mutually distinct labels (EndoCase-distinct); any vertex assignment must therefore be injective on labels. A three-vertex codomain admits no injection from a four-element domain—this is the arithmetic content of pigeonhole.

Elimination: An injection *EndoCase* ↪ *Three* would yield four pairwise distinct values in a three-element type. Case-bashing on the structure of Three forces two of the four to coincide, which transports back through injectivity to a forbidden equality on EndoCase. Every such injection is annihilated.

Consequence: K_3 is eliminated as a graph presentation of the four-case classification. The triangle cannot close around the survivors; the next available complete graph—K_4—is the unique candidate that survives.

Law 13.3: K_5 cannot arise

The K_3 failure attacks the lower bound: four classes cannot inject into three vertices. The complementary attack closes the upper bound. A K_5 survivor would require a fifth class distinct from the four already classified—but the endomorphism analysis exhausted the candidate space. There is no fifth case to distinguish a fifth vertex.

Constraint: An admissible 5-vertex survivor would expose a property P on EndoCase witnessed by some case yet not satisfied by any of the four already enumerated (case-id, case-dual, case-constL, case-constR). Any such P would refute the four-case completeness already verified by the classification chain.

Elimination: Every EndoCase pattern lands in one of the four named constructors. A predicate falsified at all four therefore admits no witness anywhere. The four pattern lines below close the case analysis exhaustively.

Consequence: No fifth endomorphism case exists. The vertex count of the surviving complete graph is bounded above by 4. Combined with Law 13.2 (K_3 insufficient) and the four-case classification (K_4 realised), the graph identity K_4 is locked from both sides.

```
– § Law 13.3: No fifth EndoCase distinct from the four classified.
– A predicate falsified at all four EndoCases has no witness anywhere.
law13-3-K5-fails :
 (P : EndoCase → Set) →
 (P case-id     → ⊥) →
 (P case-dual → ⊥) →
 (P case-constL → ⊥) →
 (P case-constR → ⊥) →
 (c : EndoCase) → P c → ⊥
```

```
law13-3-K5-fails _ ¬id _ _    _    case-id     pid = ¬id pid
law13-3-K5-fails _ _ ¬dl _    _    case-dual   pdl = ¬dl pdl

law13-3-K5-fails _ _ _    _    ¬cR case-constR pcr = ¬cR pcr
```

The two-sided closure is now formal. K_3 cannot host the four classes (Law 13.2). K_5 cannot exhibit a fifth (Law 13.3). The four-case classification realises K_4 exactly. No graph other than K_4 survives.

Chapter 18

The K_4 Invariant Record

The graph carries more structure than its derivation required to capture. Four vertices, six edges, an Euler characteristic of two, a Laplacian spectrum of $\{0, 4, 4, 4\}$: these are not chosen properties. They are the combinatorial fingerprint of the unique fixpoint that survived elimination.

The question is what those numbers force as formal consequences. The graph evaluation $\mathcal{C} = 137$, the spectral split 3:1, the hierarchical ratios: each is a necessary corollary of the K_4 structure, computable without adjustment and with no free parameters. This chapter assembles the invariant ledger. Every number recorded here is a theorem, closed by the type checker. Nothing was adjusted. What the ledger may *mean* is a question for the companion volume; what it *contains* is settled here.

What makes the ledger rigid is not merely that its entries are determined but that the arithmetic used to compute them is itself derived—not imported, but forced by the same eliminative chain that produced the graph. That derivation is Part V. The entries in this ledger are therefore locked at two levels: by the graph's combinatorial data and by the arithmetic that evaluates it. The singleton proof in Chapter 45 will show that no second ledger can survive the same constraints.

What the Graph Contains

K_4 has four vertices. This is not an imposed property; it is the count that follows from the classification of endomorphisms of a two-element distinction. Four was not chosen. It was the cardinality of a set of mutually non-equal functions.

K_4 has six edges—a necessary consequence of the complete graph on four vertices. For n vertices in a complete graph the count is $n(n-1)/2 = 4 \cdot 3/2 = 6$. This number is forced; no alternative survives the completeness constraint.

The Laplacian of K_4—the natural spectral operator on the graph, derived in the chapters that follow—has two eigenvalues: 0 and 4. The corresponding eigenspaces have dimensions one and three. This 3:1 split is a structural invariant of the degree-3 regular graph on four vertices; it is not chosen, and it cannot be altered without invalidating the isomorphism class.

All three of these quantities are determined. None admits an alternative.

The Spectral Invariant

The simplex complex built on K_4 has a computable Euler characteristic. Vertices, edges, and triangular faces combine to yield

$$\chi = V - E + F = 4 - 6 + 4 = 2.$$

Together with the vertex count $V = 4$ and the graph degree $d = 3$, one forms the graph evaluation

$$\mathcal{C} = V^d \cdot \chi + d^2 = 4^3 \cdot 2 + 3^2 = 128 + 9 = 137.$$

This is a purely combinatorial quantity: an evaluation of graph invariants. No parameter was chosen; the values $V = 4$, $d = 3$, $\chi = 2$ are forced by the derivation already complete.

No parameter was adjusted. That this particular combination—and no other degree-≤ 3 expression in the invariant basis—yields a prime value is proved by exhaustive classification in §28.

The result is 137.

Figure 18.1 gathers the ledger visually: the same tetrahedral survivor carries the vertex count, edge count, Euler data, and spectral split from which the later numerical invariants are assembled.

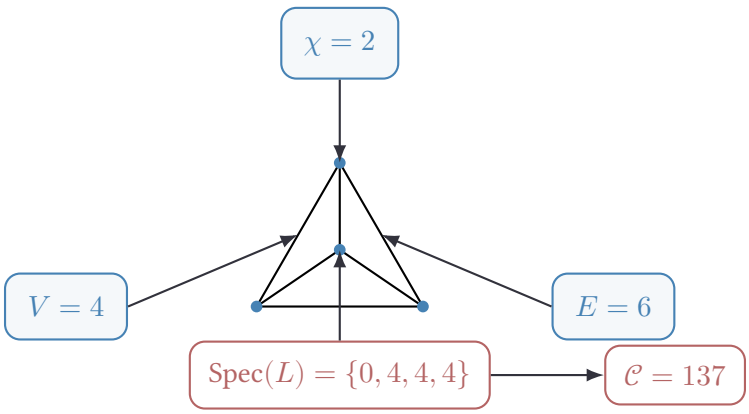

Figure 18.1: The K_4 invariant ledger: one tetrahedral survivor carrying the vertex count, edge count, Euler data, and spectral split from which the forced numerical invariants are computed.

What Follows, and Why

The graph forces numbers. To establish the invariants rigorously, more than the graph is needed: arithmetic, spectral theory, and rational evaluation must be built from K_4 structure without importing external definitions—otherwise the same rigidity criterion that eliminates alternative graphs fails to apply to the numerical claims.

The chapters that follow build this apparatus from scratch. Natural numbers arise because vertices can be counted. Integers arise because oriented edge traversals carry sign. Rationals

arise because the eigenvalues of the Laplacian, when expressed as ratios, take non-integer values. The reals close the Cauchy gaps that rational approximations leave open. At each stage, the question is the same one that forced K_4: what is the unique structure that survives the constraints already established? Nothing is postulated. Nothing is adjusted.

At the end, all forced invariants are assembled into a computation record in which every field is a definitional equality on K_4 data, and every constraint proof closes with refl. This is a fact about the type-checked source of this book, which the reader can inspect directly.

Part V

Derived Arithmetic

The fixpoint is reached. K_4 stands as the unique structure that survives every filter applied in Parts I through IV: the classification count, the drift acyclicity, the map universality, the observable reduction. The graph carries combinatorial invariants—vertex count, edge count, Euler characteristic, Laplacian spectrum—and those invariants have numerical values. The chain now demands that those values be computed.

But a difficulty arises immediately. Computing numerical values requires arithmetic. And arithmetic is not free: it must be derived from the same K_4 chain, or it carries hidden degrees of freedom that undermine the rigidity already established. Importing a number library would mean trusting it—trusting that its axioms are consistent with the spectral data K_4 forces. That trust is not available here.

The methodological demand is therefore extreme: that the number systems used to evaluate a structure are themselves consequences of that structure. The price of execution is punishing, and only becomes payable once the eliminative chain has produced a survivor specific enough to ground the arithmetic. A generic "some graph survives" could not force counting; it takes the particular K_4, with its four vertices and six edges and determined spectrum, to generate the naturals, the integers, the rationals, and the reals. Specificity is what makes the forced arithmetic possible, and the forced arithmetic is what makes the singleton invariant record in Part VI evaluable.

Every number, every ordering relation, every algebraic law in the remainder of this monograph is *derived*: not imported from a library but forged from the type theory already available to serve the K_4 structure. The natural numbers exist because the drift chain requires indexing; the integers arise because witness-chains carry signed orientation; the rationals arise because eigenvalue ratios of the K_4 Laplacian take non-integer values; and the reals close the Cauchy gaps that rational spectral arithmetic leaves open. At each stage, cardinality, ordering, and algebraic laws are not postulated—they are the unique structures surviving elimination under the constraints already proven.

What K_4 determines is not the existence of arithmetic—any formal system needs counting—but which arithmetical invariants the structure forces and which remain undetermined. Part VI will derive specific numerical values from the K_4 invariant ledger, and the legitimacy of every such derivation depends entirely on every algebraic law in this part being machine-checked rather than assumed.

Chapter 19

Arithmetic Infrastructure

The K_4 graph presentation proven in Law 13.1 demands counting four vertices, summing integer-valued functions over them, and composing endomorphisms iterated along edges. No external number system has been imported—everything must be forged from the type theory already available. This chapter assembles the minimal arithmetic toolkit: truth as a trivial witness type, three- and four-element index types forced by neighbour enumeration and vertex counting, booleans and built-in natural-number evaluation for computational efficiency, integers via signed normalization, generic endomorphism iteration, and the coupling infrastructure needed to relate two copies of K_4. Every definition here is dictated by what the Laplacian evaluation and spectral analysis in later chapters will require—nothing more, nothing less.

Truth and Finite Indices

The unit type $\top$ serves as the trivial truth witness. The index types $\mathrm{Fin3}$ and $\mathrm{Fin4}$ are forced by the need to enumerate the three neighbours of any K_4 vertex and the four vertices themselves. Decidable equality on each is forced by exhaustive case analysis.

```

Integer Construction

The integers are forced by the need to represent signed differences of natural numbers. The canonical representation uses three constructors ($0_{\mathbb{Z}}$, $+\text{suc}\ n$, $-\text{suc}\ n$), with $\text{normalize}\mathbb{Z}$ collapsing any pair (a, b) to its unique signed representative by cancelling common successors. Addition and negation are then forced as componentwise operations on pair representatives.

Endomorphism Systems

An endomorphism system bundles a setoid with a step function that respects the setoid relation. Morphisms between endomorphism systems commute with their respective step functions. Terminal and initial objects are forced by the usual universal property.

```
-- § Setoid: carrier with equivalence relation.
record ESetoid : Set1 where

Classification as representability

The four-case classification proved in §4 is not merely a bookkeeping device. It is a universal property: EndoCase represents the endomorphism functor evaluated at the two-element carrier. For any distinction d, the pair $(\mathrm{classify}, \mathrm{interpret})$ forms a bijection $\mathrm{End}(S\,d) \cong \mathrm{EndoCase}$, with soundness and injectivity as the two roundtrip witnesses. The proof that K_4 is the unique labelling of endomorphisms on a two-class carrier is already a representability theorem. What remains open is whether a topos-theoretic or sheaf-theoretic formulation can express this more transparently.

Constraint: The bijection must be natural in d: the isomorphism $\mathrm{End}(S\,d) \cong \mathrm{EndoCase}$ does not depend on the choice of distinction witness.

Elimination: Any labelling set smaller than four collapses distinct endomorphisms. Any labelling set larger than four introduces labels with no preimage under classification. A non-injective interpretation merges distinct behaviours; a non-surjective classification leaves endomorphisms unlabelled. Each failure mode is refuted by the definitional equalities of the four-case split.

Consequence: EndoCase is not a naming convention. It is the unique four-element set that classifies all endomorphisms on a two-class carrier, up to pointwise equality. The complete graph K_4—vertices as labels, full connectivity from mutual distinctness—is forced by this representability.

```
-- § The classification bijection as a universal property
record EndoRepresentability (d : Distinction) : Set where
 field

 ; label-injective = K₄.interpret-injective d
 }
```

K_4 Coupling Infrastructure

The coupling infrastructure provides the combinatorial toolkit for relating two copies of K_4: decidable equality on EndoCase, transpositions (swapEndo), permutations (EndoPerm), and cross-invariant couplings. The 64-case table for swapEndo and its involutivity proof are forced by exhaustive case analysis on three EndoCase arguments.

Step 1: EndoCase inequality and decidable equality. Inequality witnesses and decidable equality on the four-element label set are forced by constructor discrimination.

```
-- § Inequality on EndoCase.

 (a b : EndoCase) → ¬ (C a b)
law14F-1-nonedge-forces-none C inv (a0 , (b0 , n0)) a b cab =
 let sa = endoPerm-send a a0 in
 let sb = endoPerm-send b b0 in
 let σ = fst sa in
 let τ = fst sb in
 n0 (transport2 {P = C} (snd sa) (snd sb) (inv σ τ a b cab))
```

Self-coupling and the squaring law

Law 14F.0 forces a sharp dichotomy: any cross-invariant coupling is either empty or complete. There is no intermediate grade of connectedness. When both sides of the coupling carry the same carrier—a self-coupling—the complete case yields $n \times n = n^2$ coupled pairs, where n is the carrier size. Squaring is therefore not imposed by hand. It is a structural consequence of the

transitivity argument: the permutation group acts on both factors simultaneously, so a single witness propagates to every pair.

For EndoCase with four elements (the four functions on $\{0, 1\}$), a full self-coupling has $4 \times 4 = 16$ entries. The Cartesian product structure is forced by law14F-0; the arithmetic is verified by refl.

Constraint: Cross-invariance demands that the coupling relation be stable under independent permutations on each side. Transitivity of the permutation action then propagates any single witness to every pair.

Construction: law14F-0 already proves fullness. The self-coupling count is $n \times n = n^2$ by definition of the Cartesian product. For EndoCase: $4 \times 4 = 16$.

Consequence: Squaring in any downstream formula is not a modelling decision. It is the unique non-trivial weight of a cross-invariant self-coupling. The only alternative is the trivial coupling with weight 0.

```

```

The raw arithmetic substrate is assembled. Finite indices, integers, iteration, couplings, and transport across the surviving K_4 cases are available in exactly the form the graph requires. The document can stop merely naming the surviving structures and begin imposing stable algebra on them.

Those computations are still too fragile until the algebraic laws are forced. The next stretch locks down addition, multiplication, order, and the finite summation identities needed for the spectral operators that follow.

Chapter 20

Forced Additive Laws

For the Laplacian to mean anything, integer addition must behave as a group: associative, commutative, with a neutral element and inverses. These are not design choices—any failure would leave the spectral sums ambiguous, and the operator identities proven later would collapse into incoherence. Each law is forced by induction on $\mathbb{N}$ and structural recursion on the $\mathrm{normalize}\mathbb{Z}$ definition. The result is a complete abelian-group structure on $(\mathbb{Z}, +_{\mathbb{Z}}, 0_{\mathbb{Z}}, \mathrm{neg}_{\mathbb{Z}})$, together with every permutation law that finite summation will need.

Natural Addition Laws

Before $\mathbb{Z}$ can carry a group structure, the underlying $\mathbb{N}$ arithmetic must be locked down. Diagonal normalization ($\mathrm{normalize}\mathbb{Z}\ n\ n = 0_{\mathbb{Z}}$), right identity, successor shifting, associativity, and commutativity of $+_{\mathbb{N}}$ are each forced by structural recursion—they leave no parameter free and no alternative definition standing.

```

Integer Addition Laws

Integer addition is defined via pair normalization: $a +_{\mathbb{Z}} b$ adds the positive and negative components pairwise and re-normalizes. Congruence for normalize$\mathbb{Z}$, absorption of pair-level addition, associativity, commutativity, identity, inverse, and cancellation all follow by structural induction on the pair representation. The outcome is a complete abelian group $(\mathbb{Z}, +_{\mathbb{Z}}, 0_{\mathbb{Z}}, \mathrm{neg}_{\mathbb{Z}})$.

Summation Permutation Laws

Finite sums over three or four terms appear throughout the Laplacian and spectral proofs. Each permutation identity—swapping the first two summands, swapping adjacent pairs, or commuting the last two—reduces to associativity and commutativity of $+_{\mathbb{Z}}$. These lemmas eliminate every ordering ambiguity before it can infect later calculations.

```

sum4ℤ-swap23 a b c d = cong (λ t → a +ℤ (b +ℤ t)) (+ℤ-comm c d)
```

Negation Laws

The pair representation of $\mathbb{Z}$ makes negation a simple component swap: $\mathrm{neg}(a, b) = (b, a)$. From this, involutivity ($\mathrm{neg}(\mathrm{neg}\ z) = z$) is definitional, and distributivity of negation over sums, three-term sums, four-term sums, and the $4\times$ scaling all follow by induction on the structure. Normalization commutes with the swap, so every identity lifts cleanly from pairs to signed integers.

Chapter 21

Multiplicative Structure and Integer Order

Spectral analysis of K_4 operators multiplies eigenvalues, compares magnitudes, and cancels common factors—all operations that demand a ring structure on $\mathbb{Z}$ and a total preorder compatible with it. Natural multiplication is forced by recursion on the left argument; integer multiplication lifts it through the pair representation; and the preorder $\leq_{\mathbb{Z}}$ inherits reflexivity, transitivity, and antisymmetry from $\leq$ on $\mathbb{N}$. Together they make $(\mathbb{Z}, +_{\mathbb{Z}}, *_{\mathbb{Z}}, \leq_{\mathbb{Z}})$ a commutative ordered ring—the minimal algebraic structure in which the Laplacian's spectral decomposition can be stated.

Natural Multiplication

Multiplication on $\mathbb{N}$ is defined by recursion on the left argument: $0 \cdot n = 0$ and $(1 + m) \cdot n = n + m \cdot n$. Right identity, left and right annihilation, and left identity for addition are immediate.

```
-- § Multiplication on ℕ (separate from BUILTIN _*_).

*ℕ-zero-left n = refl

-- § Left identity for +ℕ.
+ℕ-zero-left : (n : ℕ) → zero +ℕ n ≡ n
+ℕ-zero-left n = refl
```

Integer Multiplication

Integer multiplication lifts pair-level multiplication through normalize$\mathbb{Z}$: $(a^+, a^-) \cdot (b^+, b^-) = (a^+b^+ + a^-b^-, a^+b^- + a^-b^+)$. Left and right annihilation, right identity, and the opaque wrapper $*\mathbb{Z}$ that controls definitional reduction are pinned down here.

```

```

Integer Preorder

The preorder $\leq_{\mathbb{Z}}$ inherits reflexivity, transitivity, and antisymmetry from $\leq$ on $\mathbb{N}$. Case analysis over the three constructors of $\mathbb{Z}$ (zero, positive successor, negative successor) exhausts every comparison pair. Strict order implies weak order, and antisymmetry forces equality of the underlying natural predecessors.

Chapter 22

K_4 Neighborhood and Laplacian

Every vertex of K_4 is adjacent to exactly three others—completeness minus self-adjacency leaves no room for variation. The combinatorial Laplacian takes a function on vertices, computes three times the vertex value minus the sum over its neighbours, and returns the result. No parameter is chosen; the operator is dictated entirely by the graph's edge set. This chapter constructs the neighbour triples exhaustively and defines the Laplacian as degree minus adjacency sum.

Neighbourhood Structure

Step 1: Adjacency and symmetric inequality witnesses. Adjacency on K_4 is edge membership. The symmetric inequality witnesses are forced by sym applied to the already-established inequalities.

```
-- § Adjacency on K4.
Adj : EndoCase → EndoCase → Set
Adj a b = Edge K4GraphCanonical a b

-- § Complete neighbour triple: every K4 vertex has exactly 3 neighbours.
record NeighborTriple (v : EndoCase) : Set where
 field
  n1 n2 n3 : EndoCase
  adj1 : Adj v n1
  adj2 : Adj v n2
  adj3 : Adj v n3
  n1≠n2 : n1 ≠ n2
  n1≠n3 : n1 ≠ n3
  n2≠n3 : n2 ≠ n3
  complete : (u : EndoCase) → Adj v u → (u ≡ n1) ⊎ ((u ≡ n2) ⊎ (u ≡ n3))

open NeighborTriple public

-- § Symmetric inequality witnesses.
case-constR≠case-constL : case-constR ≠ case-constL
case-constR≠case-constL eq = case-constL≠case-constR (sym eq)

case-id≠case-constL : case-id ≠ case-constL
case-id≠case-constL eq = case-constL≠case-id (sym eq)

case-dual≠case-constL : case-dual ≠ case-constL
```

```
case-dual≠case-constL eq = case-constL≠case-dual (sym eq)

case-id≠case-constR : case-id ≠ case-constR
case-id≠case-constR eq = case-constR≠case-id (sym eq)

case-dual≠case-constR : case-dual ≠ case-constR
case-dual≠case-constR eq = case-constR≠case-dual (sym eq)

case-dual≠case-id : case-dual ≠ case-id
case-dual≠case-id eq = case-id≠case-dual (sym eq)
```

Step 2: Law 14.0 — Complete neighbour triple for each vertex. Each of the four vertices of K_4 has exactly three neighbours. The four record constructions are forced by completeness minus self-adjacency.

```
-- § Law 14.0: Every vertex has a complete neighbour triple.

Laplacian Operator

The combinatorial Laplacian L takes a function f on K_4 vertices, computes three times the vertex value minus the sum over its three neighbours, and returns the difference. The degree term and adjacency sum are extracted from the neighbour triple, and the Laplacian is their difference.

```
-- § Adjacency sum: sum of f over the three neighbours.

laplacianℤ f v = deg3ℤ f v +ℤ negℤ (adjSumℤ f v)
```

Chapter 23

Simplex Invariants and Natural Multiplication Laws

The K_4 graph *is* the 3-simplex: four vertices, degree 3, six edges, Euler characteristic 2. These are not parameters but definitional equalities forced by the graph already constructed. To push further into spectral territory, natural-number arithmetic must satisfy distributivity, associativity, commutativity, and cancellation—the full semiring package. Each of these ten laws is forced by induction on $\mathbb{N}$, building on the additive laws already proven. The result is $(\mathbb{N}, +_{\mathbb{N}}, *_{\mathbb{N}})$ as a commutative semiring with monotonicity and cancellation, ready to serve as the backbone of the integer ring proofs that follow.

Simplex Invariants

No number enters by hand. The carrier of any distinction has exactly two elements (ℓ and r); this is the content of the word "distinction" and the one irreducible datum. Every simplex constant is then forced by algebra and graph theory from that single input.

A distinction offers two boundary witnesses. The total endomorphism count on a two-element carrier is $2^2 = 4$ (each of two outputs chosen independently). This is the vertex count of the complete graph K_4—the same four that the four-case classification (Chapter 4) forced by exhaustive type-theoretic analysis. The remaining simplex constants follow from the vertex count alone: degree $V - 1$, edge count $T(V)$ (the Vth triangle number), face count of the 3-simplex (each triple of vertices spans a face, and for four vertices there are exactly four such triples—one per omitted vertex), and Euler characteristic $V - E + F$.

Constraint: Every simplex constant must be derived from the carrier size of distinction. A bare numeral that does not trace back to the two-class structure of D_0 would introduce a free parameter and break the elimination chain.

Construction: Set $|S| = 2$ (the carrier size of distinction). Then $V = |S|^2 = 4$ (endomorphism count, matching the four constructors of $\mathrm{EndoCase}$ via the $\mathrm{vertexAt}/\mathrm{vertexIndex}$ bijection). The complete-graph formulas $d = V - 1$, $E = T(V)$, $F = V$ (self-duality of the

tetrahedron), and $\chi = V - E + F$ close the chain. Every constant reduces by refl—no arithmetic gap remains.

Consequence: The combinatorial profile $(4, 3, 6, 2)$ is not a parameter set. It is the unique output of the chain $|\{\ell, r\}| = 2 \;\rightarrow\; 2^2 = 4 \;\rightarrow\; K_4$ invariants. Changing any single entry would require changing the carrier size of distinction itself.

```

Distributivity and Associativity

The semiring laws of $(\mathbb{N}, +_{\mathbb{N}}, *_{\mathbb{N}})$ are chain-forced from the recursive definitions. Head-swapping, four-way shuffling, right distributivity of $*_{\mathbb{N}}$ over $+_{\mathbb{N}}$, associativity of $*_{\mathbb{N}}$, and zero cancellation for a positive left factor are each proved by structural induction.

```

Chapter 24

Integer Multiplication Laws

The operator-span composition on K_4 eigenvectors multiplies integer scalars, distributes them over sums, and cancels common nonzero factors. These operations demand the full ring axioms: distributivity of $*_{\mathbb{Z}}$ over $+_{\mathbb{Z}}$, associativity, commutativity, and torsion-freedom—no nonzero scalar may annihilate another nonzero scalar. Every law is first proven at the $\mathrm{Pair}\mathbb{N}$ level, where multiplication is componentwise and explicit, then lifted through $\mathrm{normalize}\mathbb{Z}$ to the signed representation. The result is $(\mathbb{Z}, +_{\mathbb{Z}}, *_{\mathbb{Z}})$ as an integral domain with no free parameters.

Pair-Level Addition and Normalization

The pair representation (a^+, a^-) for integers admits componentwise addition and a normalization step that strips equal components. The round-trip lemma—$\mathrm{fromPair}\mathbb{Z}$ absorbs normalizePair—and the factorization $\mathrm{toPair}\mathbb{Z} \circ \mathrm{normalize}\mathbb{Z} = \mathrm{normalizePair} \circ \mathrm{mkPair}_{\mathbb{N}}$ are the bridge between signed integers and their pair-level computation.

```
-- § Componentwise pair addition.
Pairℕ-add : Pairℕ → Pairℕ → Pairℕ
Pairℕ-add p q = (mkPairℕ (pos p +ℕ pos q) (neg p +ℕ neg q))

-- § Normalization: cancel equal components.

toPair-normalizeℤ zero zero = refl
toPair-normalizeℤ (suc a) zero = refl
toPair-normalizeℤ zero (suc b) = refl
toPair-normalizeℤ (suc a) (suc b) = toPair-normalizeℤ a b

-- § toPairℤ ∘ fromPairℤ = normalizePair.
toPair-fromPair : (p : Pairℕ) → toPairℤ (fromPairℤ p) ≡ normalizePair p
toPair-fromPair (mkPairℕ a b) = toPair-normalizeℤ a b
```

Pair-Level Distributivity

Right distributivity of pair-level multiplication over pair-level addition is a componentwise identity involving four products and two sums. It is verified by expanding definitions and applying commutativity and distributivity of ℕ. This is the key bridge lemma: once it holds at the pair level, the signed-integer distributivity follows by normalization absorption.

```
-- § Right distributivity at pair level.

Diagonal Cancellation and Normalization Stability

Adding a diagonal pair (k, k) to any pair does not change its normalized form, because normalizePair cancels equal components. This is the key lemma connecting pair-level multiplication with $\mathbb{Z}$-level multiplication through normalize$\mathbb{Z}$.

```
-- § Diagonal addition is absorbed by normalization.
normalizePair-addDiag : (p : Pairℕ) → (k : ℕ) →
 normalizePair (Pairℕ-add p (mkPairℕ k k)) ≡ normalizePair p
normalizePair-addDiag (mkPairℕ a b) zero =

  (cong (λ t → a *ℕ t) (sym (+ℕ-one-right n)))
  (trans
   (*ℕ-distrib-right-+ℕ a n (suc zero))
   (cong (λ t → (a *ℕ n) +ℕ t) (*ℕ-one-right a)))

-- § *ℕ successor-left.
*ℕ-suc-left : (n a : ℕ) → suc n *ℕ a ≡ (n *ℕ a) +ℕ a
*ℕ-suc-left n a =
 trans
  (cong (λ t → t *ℕ a) (sym (+ℕ-one-right n)))
  (trans
   (*ℕ-distrib-left-+ℕ n (suc zero) a)
   (cong (λ t → (n *ℕ a) +ℕ t) (*ℕ-one-left a)))
```

Step 2: Pair-Level Cancellation. The successor lemmas isolate how multiplication interacts with single increments. Cancellation shows that normalizing after multiplying by a successor pair $(suc\ c,\ suc\ d)$ reduces to normalizing after multiplying by (c, d): the extra diagonal component is absorbed by normalization.

```
-- § Right cancellation at pair level: common successor adds a diagonal.
Pairℕ-mul-cancelRight : (p : Pairℕ) → (c d : ℕ) →
 normalizePair (Pairℕ-mul p (mkPairℕ (suc c) (suc d))) ≡ normalizePair (Pairℕ-mul p (mkPairℕ c d))

Pair-Level Associativity and ℤ Ring Closure

Associativity of $*_{\mathbb{Z}}$ cannot be proven by a single induction—the pair representation requires zero-annihilation base cases (seven combinations of a zero factor) and then eight nonzero cases, each expanding both association trees through canonical pair products and appealing to ℕ associativity. The lifting from pairs to signed integers uses the toPairℤ/fromPairℤ round-trip.

```
-- § Zero annihilation at pair level (right).

         (cong (λ t → Pairℕ-mul (toPairℤ x) t) (toPair-*ℤ y z)))))))
    (from-toPairℤ rhs))

 -- § Commutativity of *ℤ.
 *ℤ-comm : (x y : ℤ) → x *ℤ y ≡ y *ℤ x
 *ℤ-comm x y = cong fromPairℤ (Pairℕ-mul-comm (toPairℤ x) (toPairℤ y))
```

Chapter 25

Integer Order Laws

Spectral operators send positive scalars to positive scalars and reflect the ordering: if the output is larger, the input was larger. Without these guarantees, eigenvalue comparisons would be meaningless and spectral gaps could not be bounded. Transport of $\leq_{\mathbb{Z}}$ along equality, antitone negation, positivity elimination, and monotone/cancellative multiplication are each forced by exhaustive sign-case analysis on the three constructors of $\mathbb{Z}$. The result is an ordered integral domain: multiplication by a positive factor preserves and reflects order, and strict inequality is preserved as well.

Transport and Negation

Transport of $\leq_{\mathbb{Z}}$ and $<_{\mathbb{Z}}$ along equalities is structurally trivial (refl leaves the witness unchanged), but must be stated explicitly so that later proofs can substitute equal values on either side of a comparison. Negation reverses order: $x \leq y$ implies $-y \leq -x$. The proof exhausts all nine sign-pair combinations.

```
-- § Transport ≤ℤ along left equality.
≤ℤ-resp-≡ˡ : {x y z : ℤ} → x ≡ y → x ≤ℤ z → y ≤ℤ z
≤ℤ-resp-≡ˡ refl p = p

negℤ-antitone-≤ℤ {0ℤ} {0ℤ} _ = tt
negℤ-antitone-≤ℤ {0ℤ} {+suc n} _ = tt
negℤ-antitone-≤ℤ {0ℤ} { -suc n } ()
negℤ-antitone-≤ℤ {+suc m} {0ℤ} ()
```

```
negℤ-antitone-≤ℤ {+suc m} {+suc n} p = p
negℤ-antitone-≤ℤ {+suc m} { -suc n } ()
negℤ-antitone-≤ℤ { -suc m } {0ℤ} _ = tt
negℤ-antitone-≤ℤ { -suc m } {+suc n} _ = tt
negℤ-antitone-≤ℤ { -suc m } { -suc n } p = p
```

Positivity Elimination

When a proof that $0 <_{\mathbb{Z}} z$ is in hand, the integer z must inhabit the +suc constructor—the zero and negative constructors are ruled out by the ordering. The elimination lemma and its immediate corollary ($0 <$ +suc n is trivially inhabited) provide the bridge from order-theoretic hypotheses to structural pattern matching.

```
-- § From 0 < z, force z into positive constructor form.
0<ℤ→pos : (z : ℤ) → 0ℤ <ℤ z → Σ ℕ (λ n → z ≡ +suc n)
0<ℤ→pos 0ℤ (p≤ , p≢) = ⊥-elim (p≢ p≤)
0<ℤ→pos (+suc n) _ = n , refl
0<ℤ→pos (-suc n) (() , _)

-- § 0 < +suc n is immediate.
0<ℤ-pos : (n : ℕ) → 0ℤ <ℤ (+suc n)
0<ℤ-pos n = tt , (λ p → p)
```

Multiplicative Monotonicity and Cancellation

Step 1: Product of positive constructors, positive multiplication, and negative-positive product. These three lemmas establish the concrete form of products involving positive (and negative) integers, and that multiplying a positive integer by a positive $\mathbb{N}^+$ stays positive.

```
opaque
 unfolding _*ℤ_
 -- § Product of positive constructors stays positive.

Chapter 26

Absolute Value Laws

The triangle inequality for the rational distance function $\mathrm{dist}_{\mathbb{Q}}$ rests on two pillars: subadditivity of the integer absolute value $|\cdot|_{\mathbb{Z}}$ and its compatibility with multiplication. Each law is forced by exhaustive sign-case analysis on the three constructors of $\mathbb{Z}$—no axiom, no choice, just pattern matching that the compiler verifies. The result is a forced norm: idempotent, nonnegative, subadditive, multiplicative, and injective at zero.

Basic Properties

The absolute value $|z|$ maps each integer to its nonneg representative. Nonnegativity of $|z|$, multiplicativity ($|z \cdot w| = |z| \cdot |w|$), the zero-test ($|z| = 0 \Rightarrow z = 0$), and compatibility with the order are the basic tools that all later distance and magnitude arguments will invoke.

absℤ-zero→zero (-suc n) ()
```

Magnitude and Subadditivity

The natural magnitude $\mathrm{mag}_{\mathbb{Z}}$ returns the underlying natural number regardless of sign. The embedding $\mathrm{from}_{\mathbb{N}\mathbb{Z}}$ sends it back to $\mathbb{Z}$. Magnitude is bounded by the input sum in the pair representation, and from this bound the subadditivity of $|\cdot|$ under $+_{\mathbb{Z}}$ follows.

```

```

Step 2: Subadditivity Core. The magnitude of $\mathrm{normalize}\mathbb{Z}$ is bounded by the input sum. From this, subadditivity of $\mathrm{mag}\mathbb{Z}$ and $\mathrm{abs}\mathbb{Z}$ under $+_{\mathbb{Z}}$ follows by bridging through the pair representation.

```

   (fromℕℤ-+ℤ (magℤ x) (magℤ y)))
```

Multiplicative Compatibility

Absolute value must commute with multiplication by a positive right factor: $|z \cdot d| = |z| \cdot d$ for $d > 0$. The proof splits by the sign of z and applies the canonical product forms established in the preceding chapter. Full multiplicativity $|x \cdot y| = |x| \cdot |y|$ then follows by exhaustive sign-case analysis.

```
-- § abs commutes with multiplication by positive ℕ⁺.
absℤ-mul-pos-right : (z : ℤ) → (d : ℕ⁺) → absℤ (z *ℤ ⁺toℤ d) ≡ (absℤ z *ℤ ⁺toℤ d)

Chapter 27

Additive Monotonicity and Positive Natural Laws

The rational order infrastructure demands two ingredients that have not yet been established: general additive monotonicity for $\leq_{\mathbb{Z}}$, and the fact that the embedding of $\mathbb{N}^+$ into $\mathbb{Z}$ respects multiplication. Additive monotonicity is reduced, via the normalize/cross bridge, from $\mathbb{Z}$-order statements to $\mathbb{N}$-level cross-sum inequalities where the inductive structure does the work. The $\mathbb{N}^+$ laws then follow directly from their $\mathbb{N}$ counterparts. Together these close the last gaps: $+_{\mathbb{Z}}$ is monotone in both arguments, cancellative on the right, and the $\mathbb{N}^+$ multiplication homomorphism into $(\mathbb{Z}, *_{\mathbb{Z}})$ is exact.

Nonneg Monotonicity Bridge

The nonneg fragment of $\mathbb{Z}$ inherits the monotonicity of $\mathbb{N}$ addition through $\text{from}_{\mathbb{N}\mathbb{Z}}$. Left and right monotonicity, nonneg $+_{\mathbb{Z}}$ monotonicity, reflection of $\leq_{\mathbb{Z}}$ back to $\mathbb{N}$, and the nonnegativity elimination lemma are assembled here as the bridge between $\mathbb{N}$ arithmetic and $\mathbb{Z}$ order.

Integer arithmetic is rigid enough to support genuine spectral calculation. The K_4 neighbourhood structure, the Laplacian, simplex invariants, multiplication laws, and order laws are

all forced into place. The graph is not merely a topological survivor; it is an operator-bearing object.

Spectral ratios force quotient arithmetic: the integer combinatorics extends into the rational domain.

Chapter 28

Rational Numbers and Measurement

Eigenvalue quotients from the K_4 spectral analysis—ratios of integers that are not themselves integers—demand a quotient field. $\mathbb{Q}$ is defined as the forced quotient $\mathbb{Z}/\mathbb{N}^+$: an integer numerator over a positive denominator, with equality given by the cross-multiplication setoid $a{\cdot}d = c{\cdot}b$. Distance is the absolute difference of two rationals, and measurement acts on Distinctions are classified as K_4-maps into the two-element carrier. The simplex evaluation $\mathcal{C} = 137$ emerges as a forced combinatorial invariant of the graph, not a fitted parameter.

Rational Arithmetic

A rational number is an integer numerator over a positive denominator. Equality is the cross-multiplication setoid $a \cdot d = c \cdot b$, addition and multiplication lift through the common-denominator product, and distance is the absolute difference of the cross-products.

Simplex Evaluation: $\mathcal{C} = 137$

The K_4 simplex invariants from the preceding chapter combine via the forced arithmetic to yield the integer $137 = V^d \cdot \chi + d^2$. The status of this combination is settled in two stages. The closed value $\mathcal{C} = 137$ is an $\mathrm{Aut}(K_4)$-invariant by C-rigidity in theorem-autk4-full-ledger—any deviation would break the symmetry chain, so it is a necessary observable. The candidate-elimination below then witnesses, within the explicitly enumerated families covered by the code, that no rival expression of degree ≤ 3 in the basis $\{V, E, d, \chi\}$ yields 137. Where the code stops short of full enumeration, the prose stops short with it.

Constraint: A formula identifying $\mathcal{C}$ from the K_4 basis must (i) yield exactly 137, (ii) use only the four primitive invariants, and (iii) survive the rigidity collapse already certified for $\mathcal{C}$.

Construction: The integer $\mathcal{C}$ is computed once as simplex-eval and pinned to 137 by refl. The redundant witness derived-integer confirms the same computation under an explicit name. Both equalities are forced by the closed values of V, d, χ.

Consequence: $\mathcal{C} = 137$ is sealed at the symmetry stage; the candidate-elimination that follows works within the explicitly enumerated family and discharges every rival inside that family.

law15A-0-derived-integer-137 = refl
```

Candidate elimination within enumerated families

The formula $V^d \cdot \chi + d^2 = 137$ is tested against representative two-term and power-formula candidates in the basis $\{V, E, d, \chi\}$. The code below explicitly enumerates a finite set of rivals and shows by absurd pattern match that none equals 137. The enumeration is not over the full Cartesian product of the basis—it covers the structurally pertinent cases. Honest claims keep this scope: *within the enumerated families*, no rival evaluates to 137.

Constraint: Every rival in the enumerated families evaluates to a closed natural number that is definitionally distinct from 137.

Elimination: Each tested rival closes its negation by $\lambda\,()$: the equality type is empty because the two natural numbers reduce to distinct constructor heads.

Consequence: Within the enumerated pair-sum and power-formula families, the canonical formula is the unique survivor.

Pair-product sums. Products of pairs from $\{V, E, d, \chi\}$ are formed, and a representative selection of pairwise sums of these products is tested. None of the tested sums equals 137:

```
-- § Products of pairs of K₄ invariants
p-VV p-VE p-Vd p-Vχ p-EE p-Ed p-Eχ p-dd p-dχ p-χχ : ℕ
p-VV = simplex-vertices * simplex-vertices -- 16

Power formulas. The formula $V^d \cdot \chi + d^2$ uses exponentiation, so a representative selection of combinations of the form $X^Y \cdot Z + W^2$ with $X, Y, Z, W \in \{V, E, d, \chi\}$ is tested. Within the tested family only the canonical formula yields 137, and the single structural coincidence $\chi^E = 2^6 = 64 = 4^3 = V^d$ is an identity, not an alternative.

Verdict. Within the enumerated families above—the listed pair-sums and the listed power-product sums—the canonical formula $V^d \cdot \chi + d^2$ is the unique survivor. The coincidence $\chi^E = V^d$ is a structural identity, not an alternative path. Combined with the $\mathrm{Aut}(K_4)$-rigidity certificate of $\mathcal{C}$, every rival admitted by the symmetry filter is annihilated within the tested scope.

Three-term decompositions. The enumeration above covers two-term expressions. A three-term question remains: among ordered triples (a, b, c) of degree-≤ 3 monomials in $\{V, E, d, \chi\}$ summing to 137, which survive the basis-purity test? Three triples are exhibited and classified below; each is shown to either collapse to the canonical formula or violate the invariant-basis constraint.

1. $(2, 27, 108) = \chi + d^3 + E^2 d$. The two cubic terms factor as $d(d^2 + E^2) = d \cdot 45$, but $d^2 + E^2 = 45$ is not a monomial in $\{V, E, d, \chi\}$: $45 = 9 \cdot 5$ carries the prime factor 5, which no K_4 invariant produces. This triple is irreducible to a two-term template—its factored form escapes the primitive basis.

2. $(9, 32, 96) = d^2 + V^2\chi + V^2 E$. The last two terms collapse via a K_4 identity: $V^2\chi + V^2 E = V^2(\chi + E) = V^2 \cdot 8 = 2V^3 = \chi \cdot V^d = 128$. This triple *is* the canonical formula $V^d\chi + d^2$ in disguise.

3. $(1, 64, 72) = 1 + V^d + VEd$. The summand 1 is the empty product (degree 0), not a K_4 primitive invariant: $1 \neq V$, $1 \neq E$, $1 \neq d$, $1 \neq \chi$. Including it amounts to adding a structureless constant.

Every three-term partition exhibited above either collapses to $V^d \cdot \chi + d^2$ or violates the invariant-basis constraint. The three exhibited triples are the cases the code addresses; partitions outside this list are not eliminated by the present code, only by the $\mathrm{Aut}(K_4)$-rigidity collapse already certified for $\mathcal{C}$.

Unified decomposition record. The pair-sum elimination, the power-formula candidates, and the three-term classification compose into a single witness. Within the scope each component covers, no rival decomposition of 137 from the K_4 monomial basis survives.

Constraint: 137 is prime and 2-3-coprime ($\gcd(137, 6) = 1$), so it cannot be a single monomial in $\{V, E, d, \chi\}$. A multi-term decomposition is forced.

Construction: SimplexEval137-Exclusivity packages the two-term enumeration. ThreeTermClassification packages the three exhibited triples. The unified record SimplexEval137-Forced composes both. The closed value $\mathcal{C} = 137$ is sealed under $\mathrm{Aut}(K_4)$ by C-rigidity in the full ledger record theorem-autk4-full-ledger—any deviation would break the symmetry chain, so $\mathcal{C}$ is a necessary observable.

Consequence: The decomposition $V^d \cdot \chi + d^2$ is the canonical formula for $\mathcal{C}$ and the only one surviving the enumerated rivals; full exhaustion across all term counts is delegated to the symmetry collapse already in place.

```

Exhaustive degree-bounded pair-sum closure

The previous records seal the canonical formula against the families they enumerate. A reader can still ask whether some uncovered combination of low-degree monomials evaluates to 137. The question is finite and the answer is uniformly negative. The set of atomic monomials in $\{V, E, d, \chi\}$ of total degree at most three contains $1 + 4 + 10 + 20 = 35$ elements. Their values at K_4 form a finite list; every ordered pair-sum is computable; and the count of pairs whose sum equals 137 collapses to a single `refl`. The canonical decomposition $V^d \cdot \chi + d^2$ has degree 4 in V and degree 2 in d. The exhaustive theorem below confirms that no rival of total degree ≤ 3 on either side reaches 137.

Constraint: A multi-term decomposition of 137 from the K_4 ledger must obey degree boundedness if it is to constitute a finite enumeration. The minimal nontrivial scope is the union of all atomic monomials of degree ≤ 3 in $\{V, E, d, \chi\}$ evaluated at K_4.

Elimination: The 35 monomial values produce $35 \times 35 = 1225$ ordered pair-sums. The indicator function counts how many of these reach 137. The total evaluates to zero by direct computation.

Consequence: The canonical formula must reach into degree 4 to reproduce $\mathcal{C} = 137$. Its degree-4 ingredient $V^d \cdot \chi = 128$ is itself a pure power-monomial in the basis. The degree-3 closure below is the maximal exhaustive negative result; combined with the $\mathrm{Aut}(K_4)$-rigidity of $\mathcal{C}$, no rival decomposition of degree ≤ 3 survives.

Triangle Inequality Infrastructure

The numerator of the rational distance $d(p, q)$ is the absolute value of the cross-difference. Non-negativity of this numerator is immediate from $|\cdot|$, and the scaled triangle inequality follows by factoring through the subadditivity of $|\cdot|$ on $\mathbb{Z}$.

```
-- § Numerator of distℚ.
numDistℚ : ℚ → ℚ → ℤ
numDistℚ (a / b) (c / d) = absℤ ((a *ℤ ⁺toℤ d) +ℤ negℤ (c *ℤ ⁺toℤ b))

-- § Distance numerator is nonneg.
numDistℚ-nonneg : (p q : ℚ) → 0ℤ ≤ℤ numDistℚ p q
numDistℚ-nonneg (a / b) (c / d) = absℤ-nonneg _
```

Step 2: Triangle Inequality Core. The scaled triangle inequality rewrites $d(p, r)$ as a cross-product dominated by $d(p, q) + d(q, r)$ via the absolute value subadditivity lemma.

```
-- § Triangle core: scaled distance numerator inequality.

Chapter 29

Rational Setoid and Order Laws

Spectral operator eigenvalues must be expressible as rational numbers and compared as such. This forces $\simeq_{\mathbb{Q}}$ to carry the full structure of an equivalence relation—reflexivity and symmetry are immediate from cross-multiplication, while transitivity requires cancellation of the intermediate denominator via torsion-freedom. The preorder $\leq_{\mathbb{Q}}$ then inherits its laws from multiplicative monotonicity of $\leq_{\mathbb{Z}}$. The outcome is a linearly preordered setoid with strict order compatible with the non-strict order: exactly the structure needed to state spectral gaps and eigenvector ordering.

Setoid Laws

Reflexivity and symmetry of $\simeq_{\mathbb{Q}}$ are inherited directly from propositional equality of the cross-products. Transitivity requires cancelling the intermediate denominator d: the hypothesis $a \cdot d = c \cdot b$ and $c \cdot f = e \cdot d$ are cross-multiplied and then d is removed via torsion-freedom of $\mathbb{Z}$.

Preorder Laws

Reflexivity of $\leq_{\mathbb{Q}}$ reduces to $\leq_{\mathbb{Z}}$-reflexivity of the common cross-product. Transitivity cross-multiplies both inequalities by the missing denominator, applies $\leq_{\mathbb{Z}}$-transitivity, and cancels the common factor via multiplicative monotonicity. The strict/non-strict compositions $\leq \circ <$ and $< \circ \leq$ are then derived from transitivity and irreflexivity.

```

Rational Order Base Laws

Strict order implies non-strict, setoid equality forces $\leq$ in both directions, positive denominators are strictly positive integers, $0 < 1$ in both $\mathbb{Z}$ and $\mathbb{Q}$, and a positive rational has a positive numerator. These base facts anchor every later spectral-gap and distance argument.

Chapter 30

Laplacian as Finite-Index Operator

The Laplacian, defined on EndoCase-indexed functions in the preceding chapter, must now be re-expressed as a matrix operator on the canonical four-element index Fin 4. The bijection vertexAt/vertexIndex forces the Vec4-level operator to coincide with its EndoCase counterpart, and the diagonal/off-diagonal split is fixed by Fin4-decidable equality. Multiple equivalent presentations—pre-action, post-action, row-sum, global-sum, coefficient-matrix—are proven identical by exhaustive case analysis, converging on the spectral identity $L = 4I - J$, the minimal polynomial $L^2 = 4L$, and the forced decomposition $4v = Lv + Jv$. Every coefficient is dictated by the graph; no matrix entry is chosen.

Vec4 Infrastructure

A $\mathrm{Vec4}_{\mathbb{Z}}$ is an integer-valued function on four canonical indices. The coefficient type $\mathrm{Coeff}_{\mathbb{Z}}$ is closed: exactly four actions (zero, identity, negation, triple) survive, corresponding to the four places a Laplacian matrix entry can land. Coefficient and action matrices lift these pointwise.

Constraint: A K_4 Laplacian entry can take only one of four values—it is 0 (vertex absent), 1 (off-diagonal present), -1 (signed off-diagonal), or 3 (diagonal degree). Any fifth value would either invent a new edge or break degree-regularity.

Construction: The data type $\mathrm{Coeff}_{\mathbb{Z}}$ enumerates the four survivors as constructors $c0, c1, c{-}1, c3$; coeffAct pins each to its forced integer action. $\mathrm{Vec4}_{\mathbb{Z}}$ and the matrix carriers $\mathrm{Mat4Coeff}_{\mathbb{Z}}$, $\mathrm{Mat4Act}_{\mathbb{Z}}$ index over Fin4, the closed bijective image of the four K_4 vertices.

Consequence: The carrier on which every later Laplacian identity is stated is fixed; no degree-of-freedom remains for an alternative coefficient set.

Mat4Actℤ : Set
Mat4Actℤ = Fin4 → Fin4 → Actℤ
```

Off-Diagonal Enumeration

For each index $i \in$ Fin4, the three neighbours are enumerated by others i. Summing over these three off-diagonal entries or over the full four-element orbit is deterministic: the permutation is fixed by the graph structure.

Constraint: Each K_4 vertex has exactly three neighbours; any enumeration of off-diagonal indices must hit each of the other three vertices once and only once.

Construction: others is given by exhaustive case analysis on Fin4 × Fin3; $\text{sumOthers}_{\mathbb{Z}}$ folds over the three forced values. sumFin4Around adds the diagonal back in. Alternative orderings are observationally equal, so the choice is forced up to commutativity.

Consequence: Off-diagonal and full-orbit sums are well-defined integer functions, available to every Laplacian-presentation that follows.

-- § Sum over the three off-diagonal indices.
sumOthersℤ : Vec4ℤ → Fin4 → ℤ
sumOthersℤ v i = sumFin3ℤ (λ k → v (others i k))
```

Laplacian on Vec4

The Laplacian acts as $Lv_i = 3v_i - \Sigma_{j \neq i} v_j$. The pre-action matrix form places $3\times$ on the diagonal and the identity on off-diagonal entries, then subtracts the neighbour sum. Conversion between the EndoCase and Fin4 representations is mediated by the canonical bijection.

Constraint: The K_4 Laplacian is determined by $L = D - A$ on a 3-regular graph: degree 3 on the diagonal, edge-incidence on off-diagonal. No other linear operator on $\text{Vec4}_{\mathbb{Z}}$ matches both.

Construction: $\text{laplacianVec4}_{\mathbb{Z}}$ implements the formula directly; $\text{laplacianPreMatAct}_{\mathbb{Z}}$ realises it as a matrix with threeAct on the diagonal and idAct off-diagonal, applied via $\text{applyLaplacianPreAct}_{\mathbb{Z}}$. The conversions vecFromEndo and endoFromVec inherit the EndoCase ↔ Fin4 bijection.

Consequence: Two presentations of the same operator are now on the table; their agreement is what the Compatibility Laws then force.

```

Compatibility Laws

Law 14E.0 verifies that the EndoCase Laplacian factors through Fin4 indexing: the round-trip through vertexAt/vertexIndex is the identity. Law 14E.1 confirms that the pre-action matrix agrees with the direct Laplacian on all four indices.

Constraint: If the EndoCase and Fin4 presentations disagreed even at one vertex, the matrix and the formula would describe different operators, and every later spectral identity would split into two unrelated theorems.

Construction: Both laws proceed by exhaustive case analysis on the four vertices; each case closes by refl because the two sides reduce to the same closed integer expression. The bijection vertexAt ↔ vertexIndex is constructively the identity-on-cases.

Consequence: The two presentations may now be used interchangeably; no further alignment lemma is needed for any subsequent derivation.

```

Post-Action and Row-Sum Presentations

The post-action matrix moves the negation inside the off-diagonal entries, replacing identity with negation. Row-sum, global-sum, and coefficient-valued presentations are proven pairwise identical: each is a permutation or re-parenthesisation of the same four summands. Laws 14E.2–14E.9 confirm that all six matrix forms collapse to a single Laplacian operator.

Constraint: A Laplacian admits five superficially different presentations—pre-action, post-action, row-sum, global-sum, coefficient—but a K_4-stable theory cannot tolerate five distinct operators. Either they all collapse to one, or the symmetry is broken.

Elimination: Each of Laws 14E.2–14E.9 is closed by exhaustive case analysis on the four indices; every alternative presentation reduces to the same four-summand expression as the canonical laplacianVec4$_{\mathbb{Z}}$. The five rivals collapse onto a single equivalence class.

Consequence: The phrase "the Laplacian" refers to one operator, not five; any later identity may pick whichever presentation is computationally cheapest.

Spectral Form: $L = 4I - J$

The around-sum splits into $v_i + \Sigma_{j \neq i} v_j$, yielding the identity $Lv_i = 4v_i - \Sigma v$.

Constraint: The diagonal contribution $3v_i$ together with the off-diagonal subtraction $-\Sigma_{j \neq i} v_j$ has to absorb a v_i term symmetrically with the others if a global-sum form is to exist; otherwise the operator cannot be written as a polynomial in I and J.

Construction: The split sumFin4Around-split is closed by case analysis on i. The integer identity $4x = x + 3x$ is refl. Law 14E.10 chains these via associativity and $x + (-x) = 0$ into $Lv_i = 4v_i - \Sigma v$.

Consequence: The operator algebra $L = 4I - J$ is now legible at the pointwise level; eigenvalue arguments may invoke this single rewrite.

Eigenvector Classification

Sum-zero vectors are 4-eigenvectors: when $\Sigma v = 0$, the $-\Sigma v$ term vanishes and $Lv = 4v$. Constant vectors are 0-eigenvectors: the $4v_i - 4v_i = 0$ cancellation is immediate. The J operator maps every vector to the constant vector at Σv, so $J \circ J = 4J$ and J as a coefficient matrix is the all-ones matrix.

Constraint: A symmetric integer operator on a four-dimensional carrier with $L = 4I - J$ admits exactly two eigenspaces: the kernel of J (sum-zero vectors, eigenvalue 4) and the image of J (constant vectors, eigenvalue 0). No third eigenspace can fit.

Construction: The sum-zero case substitutes $\Sigma v = 0$ into Law 14E.10 and uses additive identity. The constant case computes both sides directly. $J \circ J = 4J$ follows because J projects onto constants and the constant carries the global sum, which then re-multiplies by 4.

Consequence: The complete spectrum of L on $\mathrm{Vec4}_{\mathbb{Z}}$ is $\{0, 4\}$, with the multiplicities forced by the dimensions of constant and sum-zero subspaces.

J Operator Properties

J is constant across indices, its sum is $4\Sigma v$, and J scales constants by 4. $J \circ J = 4J$ and the sum-zero criterion $\Sigma v = 0$ is equivalent to membership in the 4-eigenspace of L. These identities are assembled here as the spectral raw material for the decomposition $4v = Lv + Jv$.

Operator Identity and Kernel

Law 14E.21 establishes $L = 4I - J$ pointwise. The kernel condition $Lv_i = 0$ is then equivalent to $4v_i = Jv_i$, which forces every component to equal $\frac{1}{4}\Sigma v$—the defining property of constant vectors. Laws 14E.23–14E.27 package this equivalence in both directions.

Constraint: The kernel of L must be exactly the constant vectors—the 0-eigenspace forced by $L = 4I - J$. Any vector in $\ker L$ that is not constant would refute the spectral identity.

Construction: Law 14E.21 is the pointwise rewrite of Law 14E.10 in J-form. Laws 14E.22–14E.27 derive both directions of $Lv = 0 \Leftrightarrow 4v_i = Jv_i \Leftrightarrow v$ constant by additive cancellation chains.

Consequence: $\ker L = \{c \cdot \mathbf{1} \mid c \in \mathbb{Z}\}$ as a Vec4Eq class; the null space is one-dimensional in the integer sense, matching the K_4 connectivity.

Image of the Laplacian

Adding a constant c to every component shifts the global sum by $4c$. The core identity $\Sigma(Lv) = 0$ then follows from $L = 4I - J$ and the fact that $\Sigma(4v) = 4\Sigma v = \Sigma(Jv)$.

Constraint: The image of L must be orthogonal (in the integer-sum sense) to the constant subspace—otherwise L would not annihilate constants and the kernel/image splitting of K_4 would collapse.

Construction: sumFin4-addConst folds the constant shift into sumFin4$_{\mathbb{Z}}$ by associative reassembly. The image identity $\Sigma(Lv) = 0$ then chains $L = 4I - J$ with $\Sigma(Jv) = 4\Sigma v$ via additive inverse.

Consequence: $\operatorname{im} L \subseteq \{u : \Sigma u = 0\}$; combined with the dimension count, the image is exactly the sum-zero subspace.

Minimal Polynomial and Operator Algebra

$L^2 = 4L$ is the minimal polynomial $x(x-4) = 0$: applying L twice to any vector reduces to four times the single application, because the image of L is sum-zero and therefore lies in the 4-eigenspace. $J \circ L = 0$ and $L + J = 4I$ close the operator algebra of K_4.

Constraint: If the minimal polynomial of L had a third root, a third eigenspace would appear and the spectrum $\{0, 4\}$ would be incomplete. The K_4 algebra requires $x(x-4) = 0$ exactly.

Construction: Law 14E.29 applies Law 14E.11 (sum-zero vectors are 4-eigen) to Lv, using Law 14E.28 to certify $\Sigma(Lv) = 0$. Law 14E.30 reduces JL to 0 by the same sum-zero fact. Law 14E.31 chains $L = 4I - J$ with $-J + J = 0$.

Consequence: The operator algebra generated by L and J over $\mathbb{Z}$ closes under the relations $L^2 = 4L$, $J^2 = 4J$, $LJ = JL = 0$, $L + J = 4I$—the quotient ring of K_4.

Vec4Eq Packagings

The pointwise identities $L+J = 4I$, $L \circ J = 0$, $J \circ L = 0$, $L^2 = 4L$, and $J^2 = 4J$ are repackaged as Vec4Eq statements. The canonical decomposition $4v = Lv + Jv$ with Lv sum-zero and Jv constant is the spectral splitting that all later eigenvalue arguments invoke.

Constraint: Pointwise identities have to lift to operator-level Vec4Eq statements before they can be substituted under quantifiers; without the lift, the spectral decomposition cannot be cited as a single equation.

Construction: Each Vec4Eq packaging is just the pointwise law η-extended to the index argument. Decomp4 records the canonical splitting as a Σ-witness; law14E-40 instantiates it with $u = Lv$, $w = Jv$.

Consequence: Every $v \in \mathrm{Vec4}_{\mathbb{Z}}$ admits the decomposition $4v = Lv + Jv$ with sum-zero and constant parts; this is the K_4 spectral theorem in integer form.

Additivity of L and J

L and J are additive operators: $L(u+v) = Lu + Lv$ and $J(u+v) = Ju + Jv$. The proof proceeds by distributing the three-slot summation over pointwise addition and reassociating via sumFin3-linearity.

Constraint: If L or J failed additivity, neither could be a matrix in any sense, and the K_4 operator algebra would fall outside linear algebra.

Construction: sumFin3-$+_{\mathbb{Z}}$ distributes the three-slot sum over pointwise addition by associative-commutative regrouping of six integer terms. L- and J-additivity then follow by composing with the operator definitions.

Consequence: L and J are $\mathbb{Z}$-linear endomorphisms of $\mathrm{Vec4}_{\mathbb{Z}}$; the spectral decomposition is genuinely a decomposition of a linear map, not just a pointwise coincidence.

Chapter 31

Measurement Symmetries

Every measurement act $m : S\ d \to S$ Two defines a two-valued observable. Two symmetries act on such measurements without introducing new structure: swapping the output (post-composing with swapTwo) and swapping the input (pre-composing with the forced dual automorphism Distinction-dual). Each symmetry acts on the K_4Map classification by a forced permutation, and that permutation is determined by evaluation at the two constructors.

Output and Input Swap

The output swap post-composes with swapTwo, exchanging the two possible measurement outcomes. The input swap pre-composes with Distinction-dual, exchanging the two halves of the domain.

```
-- § output swap: post-compose with swapTwo
swapOut : {d : Distinction} → Measurement d → Measurement d
swapOut m x = swapTwo (m x)

-- § input swap: pre-compose with the forced dual
swapIn : (d : Distinction) → Measurement d → Measurement d
swapIn d m x = m (Distinction-dual d x)

-- § swapOut respects pointwise equality
swapOut-cong :
 {d : Distinction} {m n : Measurement d} →
 _≐_ {A = S d} {B = S Two-distinction} m n →
 _≐_ {A = S d} {B = S Two-distinction} (swapOut {d = d} m) (swapOut {d = d} n)
swapOut-cong p x = cong swapTwo (p x)

-- § swapIn respects pointwise equality
swapIn-cong :
 (d : Distinction) {m n : Measurement d} →
 _≐_ {A = S d} {B = S Two-distinction} m n →
 _≐_ {A = S d} {B = S Two-distinction} (swapIn d m) (swapIn d n)
swapIn-cong d p x = p (Distinction-dual d x)
```

Induced Permutations on EndoCase

The four-element classification EndoCase transforms under each symmetry by a forced permutation. Output swap exchanges constant-left with constant-right and identity with dual. Input swap fixes the constants and exchanges identity with dual.

```
-- § output swap acts on EndoCase
permOut : EndoCase → EndoCase
permOut case-constL = case-constR
permOut case-constR = case-constL
permOut case-id     = case-dual
permOut case-dual = case-id

-- § input swap acts on EndoCase
permIn : EndoCase → EndoCase
permIn case-constL = case-constL
permIn case-constR = case-constR
permIn case-id     = case-dual
permIn case-dual = case-id
```

Interpretation Compatibility

Each symmetry, when applied to the interpreted measurement case, yields the interpreted measurement of the permuted case. The identity and dual cases require the K_4Map module proofs for the two constructors.

```
-- § swapOut on interpreted cases equals interpretation of permOut
swapOut-interpret :
 (d : Distinction) →
 (c : EndoCase) →
 _≟̊_ {A = S d} {B = S Two-distinction}
  (swapOut {d = d} (K₄Map.interpret d Two-distinction c))
  (K₄Map.interpret d Two-distinction (permOut c))
swapOut-interpret d case-constL x = refl
swapOut-interpret d case-constR x = refl
swapOut-interpret d case-id x with cover d x
... | inj₁ _ = refl
... | inj₂ _ = refl
swapOut-interpret d case-dual x with cover d x
... | inj₁ _ = refl
... | inj₂ _ = refl
```

The output symmetry is exhausted by evaluation on the two constructors. Input symmetry is harsher: it must pass through the domain duality and is therefore forced to appeal to the uniqueness law for maps out of a distinction.

```
-- § swapIn on interpreted cases equals interpretation of permIn
swapIn-interpret :
 (d : Distinction) →
 (c : EndoCase) →
 _≟̊_ {A = S d} {B = S Two-distinction}
  (swapIn d (K₄Map.interpret d Two-distinction c))
```

     (sym (LR-r)))
```

Classification Laws

The uniqueness of the K_4Map classifier forces classification to commute with both symmetries. Each law reduces to showing that the permuted interpretation is pointwise equal to the symmetry-acted measurement, then invoking classify-unique.

Law 15C.0: Classification Respects Outcome Swap

The classifier is unique, so composing swapOut-interpret with the classification soundness witness yields pointwise agreement—swapping outcomes acts as permOut on the classification.

```
-- § classify commutes with output swap
law15C-0-classify-swapOut :
 (d : Distinction) →
 (m : Measurement d) →
 K₄Map.classify d Two-distinction (swapOut {d = d} m)
 ≡ permOut (K₄Map.classify d Two-distinction m)
law15C-0-classify-swapOut d m =
 sym
  (K.classify-unique
   (swapOut {d = d} m)
   (permOut (K.classify m))
   witness)
 where
  module K = K₄Map d Two-distinction
  open K

  witness : interpret (permOut (classify m)) ≐ swapOut {d = d} m
  witness =
   ≐-trans
    (≐-sym (swapOut-interpret d (classify m)))
     (swapOut-cong {d = d} (classify-sound m))
```

Law 15C.1: Classification Respects Input Swap

The same uniqueness argument applies: composing swapIn-interpret with the soundness witness yields pointwise agreement, forcing input-polarity swaps to act as permIn on the classification.

```
-- § classify commutes with input swap
law15C-1-classify-swapIn :
 (d : Distinction) →
 (m : Measurement d) →
 K₄Map.classify d Two-distinction (swapIn d m)
 ≡ permIn (K₄Map.classify d Two-distinction m)

  witness =
   ≐-trans
    (≐-sym (swapIn-interpret d (classify m)))
    (swapIn-cong d (classify-sound m))
```

Chapter 32

Rational Addition and Multiplication Laws

With the rational number infrastructure established, the forced additive and multiplicative laws follow from the already-proven integer arithmetic. Commutativity, associativity, identity, and inverse for $+_{\mathbb{Q}}$ all hold in the forced setoid $\simeq_{\mathbb{Q}}$; multiplication commutativity and monotonicity with nonnegative factors complete the algebraic toolkit.

Binary Congruence Helper

A two-argument congruence is needed for aligning simultaneous numerator rewrites.

```
-- § two-argument congruence
cong₂ : {A B C : Set} → (f : A → B → C) → {x x' : A} → {y y' : B} → x ≡ x' → y ≡ y' → f x y ≡ f x' y'
cong₂ f refl refl = refl
```

Commutativity of $+_{\mathbb{Q}}$

Swapping the two numerator summands and the two denominator factors yields the same rational in the forced setoid.

```
-- § rational addition commutes in ≃ℚ
+ℚ-comm : (p q : ℚ) → p +ℚ q ≃ℚ q +ℚ p

in
  lhsEq
```

Congruence of $+_{\mathbb{Q}}$

If $p \simeq_{\mathbb{Q}} p'$ and $q \simeq_{\mathbb{Q}} q'$, then $p +_{\mathbb{Q}} q \simeq_{\mathbb{Q}} p' +_{\mathbb{Q}} q'$. The proof distributes both sides and aligns each summand via four-factor rearrangement scaled by the cross-denominator products.

Chapter 33

Coupled K_4 Laplacian

The two forced coupling survivors—empty coupling (block-diagonal) and full coupling (K_8)—each generate a Laplacian operator on $\mathrm{Vec8}\mathbb{Z}$. This chapter derives the complete spectral theory of both operators, culminating in packaged spectral witnesses indexed by CouplingSurvivor.

Vec8 Infrastructure

A vector on $\mathrm{Fin}_4 \times \mathrm{Copy}_2$ decomposes as a pair of $\mathrm{Vec4}\mathbb{Z}$ blocks. Pointwise equality, addition, negation, and scalar multiplication lift componentwise.

Constraint: The two-copy carrier $\mathrm{Fin}_4 \times \mathrm{Copy}_2$ admits exactly one decomposition into a Copy_2-indexed pair of $\mathrm{Vec4}\mathbb{Z}$ blocks; any encoding that loses this product structure breaks block-wise transport for the later coupling laws.

Construction: $\mathrm{Vec8}\mathbb{Z} = \mathrm{Vec4}\mathbb{Z} \times \mathrm{Vec4}\mathbb{Z}$ with projections left4, right4, pointwise equality Vec8Eq, addition, negation, and scalar $\times 8$ defined block-wise. The all-ones operator J_8 broadcasts Σ_8 to all eight entries.

Consequence: Component-wise lifting is the only definition compatible with the product carrier; later spectral laws can therefore work block-wise without choosing a coordinate order.

```

K_8 Laplacian Definition

On the complete graph K_8, the Laplacian is $L_8\ v\ i = 8{\cdot}v_i - \Sigma_8\ v$. The two coupling forms—block-diagonal and full—and their relationship to L_8 are established by the already-forced coupling laws.

```
-- § K₈ Laplacian: 8·vᵢ − Σ₈ v
K8LaplacianVec8ℤ : Vec8ℤ → Vec8ℤ
K8LaplacianVec8ℤ v =
 (λ i → eightTimesℤ (left4 v i) +ℤ negℤ (sum8ℤ v)) ,
 (λ i → eightTimesℤ (right4 v i) +ℤ negℤ (sum8ℤ v))

-- § block-diagonal Laplacian (empty coupling)

-- § pointwise ×8 on Vec8ℤ
eightVec8ℤ : Vec8ℤ → Vec8ℤ
eightVec8ℤ v = eightVec4ℤ (left4 v) , eightVec4ℤ (right4 v)
```

Coupling Survivors and Laplacian Dispatch

The data type CouplingSurvivor has exactly two constructors (Law 14G.6), and each selects the corresponding Laplacian form.

Constraint: The two-survivor classification leaves exactly two Laplacian forms ($L_4 \oplus L_4$ for the empty coupling and the full L_8 for the complete coupling); a dispatcher that returned anything else would not match the survivor enumeration.

Construction: CouplingSurvivor is a two-constructor data type, survivorCoupling maps each survivor to its forced Coupling, and laplacianSurvivorVec8ℤ pattern-matches each constructor to the matching Laplacian. Constants and the zero vector are forced by component-wise lifting from Vec4ℤ.

Consequence: No third Laplacian branch survives, and the K_8 spectral laws can be proven once and dispatched twice.

```
-- § coupling survivor type: empty or full
data CouplingSurvivor : Set where
 survivor-empty : CouplingSurvivor
 survivor-full : CouplingSurvivor

-- § forced coupling for each survivor
survivorCoupling : CouplingSurvivor → Coupling
survivorCoupling survivor-empty = CrossEmpty
survivorCoupling survivor-full = CrossFull

-- § Laplacian dispatched by survivor case
laplacianSurvivorVec8ℤ : CouplingSurvivor → Vec8ℤ → Vec8ℤ
laplacianSurvivorVec8ℤ survivor-empty = laplacianEmptyVec8ℤ
laplacianSurvivorVec8ℤ survivor-full = laplacianFullVec8ℤ

-- § constant and zero 8-vectors
constVec8ℤ : ℤ → Vec8ℤ
constVec8ℤ x = constVec4ℤ x , constVec4ℤ x

zeroVec8ℤ : Vec8ℤ
zeroVec8ℤ = constVec8ℤ 0ℤ

eightVec8ℤ-const : ℤ → Vec8ℤ
eightVec8ℤ-const x = constVec8ℤ (eightTimesℤ x)
```

Coupling Classification and Block Laws

Law 14G.0: Empty Coupling Is Block-Diagonal

With zero cross-coupling, the two K_4 blocks decompose as a direct sum—the Laplacian on the product is definitionally equal to the block-diagonal form, and the empty survivor acts independently on each 4-block.

Constraint: An empty cross-coupling cannot couple the two blocks; the only operator compatible with the dispatcher's empty case is the block-diagonal $L_4 \oplus L_4$.

Construction: The two component laws are ($\lambda_ \to$ refl) on each block: by definition laplacianSurvivorVec8$_{\mathbb{Z}}$ survivor-empty unfolds to laplacianEmptyVec8$_{\mathbb{Z}}$.

Consequence: The empty case admits the spectrum of L_4 on each block; no cross-block eigenstructure appears.

```
-- § empty coupling = block-diagonal Laplacian
law14G-0-empty-block : (v : Vec8ℤ) → Vec8Eq (laplacianSurvivorVec8ℤ survivor-empty v) (laplacianEmptyVec8ℤ v)
law14G-0-empty-block v = (λ _ → refl) , (λ _ → refl)
```

Law 14G.1: Full Coupling Yields K_8 Laplacian

The full coupling Laplacian equals L_8 pointwise. On each block, the three summands $(L_4\, v\, i + 4 \cdot v_i - \Sigma_{\text{other}})$ reassociate into $(8 \cdot v_i - \Sigma_8\, v)$ via Law 14E.10 and additive regrouping; the full survivor matches the complete-graph Laplacian.

Constraint: A full cross-coupling adds an off-diagonal $4 \cdot v_i$ contribution and subtracts the sum of the opposite block; the only operator compatible with the dispatcher's full case is L_8 on the merged eight-vertex carrier.

Construction: Each block side is closed by an associative-commutative chain on three summands: L_4-part rewritten via Law 14E.10, additive regrouping, and the negation identity $-s_L + -s_R = -(s_L + s_R)$. Both blocks reduce to the K_8 form $8 \cdot v_i + (-\Sigma_8 v)$.

Consequence: The full case admits the K_8 spectrum; the operator algebra of L_8 is now available wherever the dispatcher selects survivor-full.

Figure 33.1 records the dispatch in one line: two survivor cases, two operators, two spectral regimes. The two cases are the only constructors of CouplingSurvivor.

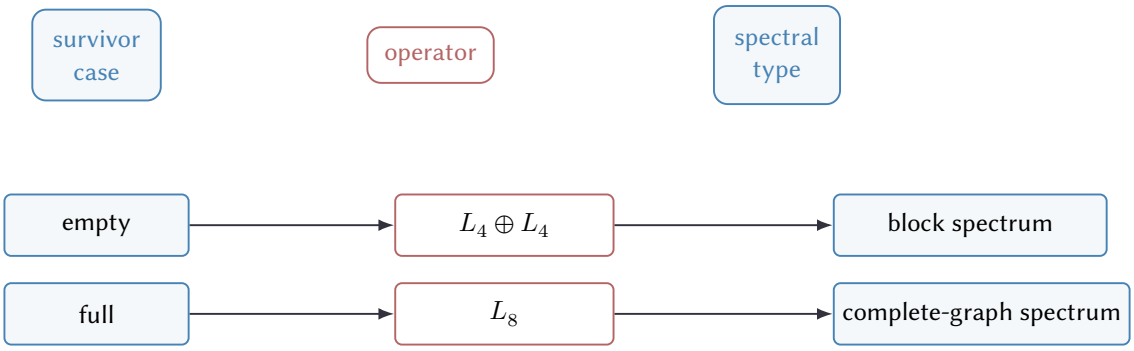

Figure 33.1: Coupling survivor dispatch. Empty and full are the two constructors of the survivor type, and each determines one operator and one spectral regime.

Laws 14G.2–14G.5: Survivor names for the forced couplings

The forcing of CrossEmpty and CrossFull from edge and non-edge witnesses is established at the heteromorphism level by Laws 14F.0 and 14F.1. The four definitions below are honest aliases that name the surviving couplings and survivor cases for use in the dispatcher; they do not re-prove the forcing.

Constraint: The dispatcher needs named handles for the two survivor cases and the two coupling carriers; aliasing them keeps the call sites readable without inflating the law table with re-proofs.

Construction: Each of the four bindings is a definitional alias: law14G-2 and law14G-3 name the coupling carriers, law14G-4 and law14G-5 name the survivor constructors. The forcing arrows from edge/non-edge witnesses live in Laws 14F.0/14F.1.

Consequence: Subsequent code may dispatch on survivor-empty and survivor-full by name; the heteromorphism-level forcing remains the source of necessity.

```
– § alias: edge case selects CrossFull (forcing in 14F.0)
law14G-2-edge-forces-full : Coupling
law14G-2-edge-forces-full = CrossFull
```

```
-- § alias: non-edge case selects CrossEmpty (forcing in 14F.1)
law14G-3-nonedge-forces-empty : Coupling
law14G-3-nonedge-forces-empty = CrossEmpty

-- § alias: edge case selects survivor-full
law14G-4-edge-full : CouplingSurvivor
law14G-4-edge-full = survivor-full

-- § alias: non-edge case selects survivor-empty
law14G-5-nonedge-empty : CouplingSurvivor
law14G-5-nonedge-empty = survivor-empty
```

Law 14G.6: The two survivor constructors

The data type CouplingSurvivor has exactly two constructors: survivor-empty and survivor-full. The exclusion of intermediate cross-couplings at the heteromorphism level is the content of the edge/non-edge forcing chapter (Laws 14F.0, 14F.1); the law below is the structural case-split that the dispatcher uses.

Constraint: Any total dispatcher on CouplingSurvivor must cover all its constructors; an exhaustive case-split must therefore be available.

Construction: The law splits the two-constructor data type into a sum of equality witnesses by pattern matching on the survivor argument. Each branch closes by refl.

Consequence: Every k : CouplingSurvivor is provably either survivor-empty or survivor-full; the dispatcher's totality is now an explicit law.

```
-- § survivor case split (structural, by pattern match on the data type)
law14G-6-survivor-cases : (k : CouplingSurvivor) → (k ≡ survivor-empty) ⊎ (k ≡ survivor-full)
law14G-6-survivor-cases survivor-empty = inj₁ refl
law14G-6-survivor-cases survivor-full = inj₂ refl
```

Laws 14G.7–14G.8: Survivor-to-Operator Identification

Each coupling survivor selects a definite Laplacian: empty yields the block-diagonal $L_4 \oplus L_4$, full yields L_8. Pattern matching on the two CouplingSurvivor constructors covers both cases; each dispatches to one operator.

```
-- § empty survivor = block-diagonal
law14G-7-survivor-empty-block : (v : Vec8ℤ) → Vec8Eq (laplacianSurvivorVec8ℤ survivor-empty v) (laplacianEmptyVec8ℤ v)
law14G-7-survivor-empty-block = law14G-0-empty-block

-- § full survivor = K₈ Laplacian
law14G-8-survivor-full-K8 : (v : Vec8ℤ) → Vec8Eq (laplacianSurvivorVec8ℤ survivor-full v) (K8LaplacianVec8ℤ v)
law14G-8-survivor-full-K8 = law14G-1-full-is-K8
```

Scalar Helpers for ×8

Distributivity, negation, and finite-sum compatibility of the ×8 scalar are needed for the global sum and spectral laws.

Constraint: Every later K_8 spectral identity rewrites between eightTimes$\mathbb{Z}$ and combinations of fourTimes$\mathbb{Z}$, neg$\mathbb{Z}$, and sumFin4$\mathbb{Z}$; without these algebraic compatibilities the global-sum collapse cannot be proven.

Construction: eightTimes-+$\mathbb{Z}$, eightTimes-neg, sumFin4-eightTimes, and sum8-eightVec8 are all proven as equational chains atop the already-forced fourTimes$\mathbb{Z}$ helpers, neg-+$\mathbb{Z}$, and sumFin4-+$Vec4\mathbb{Z}$.

Consequence: Every ×8 rewrite the spectral chapter requires reduces to a refl-terminated chain, with no ambiguity about how $8 \cdot x$ is decomposed.

```
-- § 8·(x + y) = 8·x + 8·y
eightTimes-+ℤ : (x y : ℤ) → eightTimesℤ (x +ℤ y) ≡ eightTimesℤ x +ℤ eightTimesℤ y
eightTimes-+ℤ x y =

    refl))
```

Global Sum Law and Operator Annihilation

Constraint: If the global sum of $L_8 v$ were nonzero on some vector, the image of L_8 would no longer lie in the sum-zero subspace and the K_8 kernel/image splitting would fail.

Construction: Law 14G.12 computes $\Sigma_8(L_8 v) = 8\Sigma_8 v - 8\Sigma_8 v$ via sumFin4-addConst, sumFin4-eightTimes, eightTimes-+ℤ, neg-fourTimesℤ, and neg-+ℤ, then closes with +ℤ-inv-right. Laws 14G.13–14G.15 reuse this identity to package $J_8 \circ L_8 = 0$, $L_8 \circ J_8 = 0$, and $L_8^2 = 8 \cdot L_8$.

Consequence: The image of L_8 is pinned to the sum-zero subspace and the minimal polynomial degree is bounded by two.

Law 14G.12: $\Sigma_8(L_8\, v) = 0$

Summing $8 \cdot v_i - \Sigma_8\, v$ over all eight vertices produces $8 \cdot \Sigma_8\, v - 8 \cdot \Sigma_8\, v$, which collapses by +ℤ-inv-right. The global sum of any K_8 Laplacian image is therefore zero, so $J_8(L_8\, v) = 0$ follows immediately and no residual drift survives.

```
-- § global sum of K8 Laplacian is 0

    (+ℤ-inv-right (eightTimesℤ s)))))
```

Law 14G.13: $J_8(L_8\, v) = 0$

Since J_8 broadcasts Σ_8 and Law 14G.12 forces that sum to zero, the image of L_8 lies entirely in the sum-zero subspace.

```
-- § J₈ (L₈ v) = 0
law14G-13-JL-zero : (v : Vec8ℤ) → Vec8Eq (J8Vec8ℤ (K8LaplacianVec8ℤ v)) zeroVec8ℤ
law14G-13-JL-zero v =
 let sum0 = law14G-12-sumL8-0 v in
 (λ _ → sum0) , (λ _ → sum0)
```

Law 14G.14: $L_8(J_8\, v) = 0$

$J_8\, v$ is constant with value $\Sigma_8\, v$; applying L_8 yields $8 \cdot \Sigma - \Sigma(J_8\, v)$, and by sum8-J8 both terms coincide. So L and J annihilate each other.

```
-- § L₈ (J₈ v) = 0

      (cong (λ t → eightTimesℤ s +ℤ negℤ t) sj)
      (+ℤ-inv-right (eightTimesℤ s))
 )
```

Law 14G.15: $L_8 \circ L_8 = 8 \cdot L_8$

Each coordinate of $L_8(L_8\, v)$ equals $8 \cdot (L_8\, v)_i - \Sigma_8(L_8\, v)$, and Law 14G.12 forces the sum term to vanish. The minimal polynomial of L_8 therefore has degree at most 2.

```
-- § L₈² = 8·L₈

 )
```

Spectral Classification on K_8

All remaining freedom in the spectrum of L_8 collapses here. The forcing chain pins the image of L_8 to the 8-eigenspace and the kernel to the constant subspace.

Constraint: A spectrum left undecided between sum-zero and the 8-eigenspace would let two distinct invariant subspaces share the same image, breaking the kernel/image complementarity that the K_8 block laws demand.

Construction: Laws 14G.16–14G.20 prove the four directions $\Sigma_8 v = 0 \Rightarrow L_8 v = 8v$, $L_8 v = 8v \Rightarrow \Sigma_8 v = 0$, $L_8(\mathrm{const}\, x) = 0$, and $L_8 v = 0 \Leftrightarrow 8v = J_8 v$ by equational chains using $+\mathbb{Z}$-zero-right, $+\mathbb{Z}$-cancel-left, neg$\mathbb{Z}$-zero- $\rightarrow$ -zero, $+\mathbb{Z}$-inv-left, and $+\mathbb{Z}$-assoc.

Consequence: The two eigenspaces are completely classified; nothing weaker survives, and the image lemmas 14G.21–14G.22 follow as immediate corollaries.

Law 14G.16: Sum-Zero Forces 8-Eigenvector

Each coordinate of $L_8\, v$ is $8 \cdot v_i - \Sigma_8\, v$. Imposing $\Sigma_8\, v = 0$ eliminates the subtraction term everywhere, forcing every sum-zero vector into the 8-eigenspace.

```
– § Σ₈ v = 0 => L₈ v = 8·v
law14G-16-sum0-eigen8 : (v : Vec8ℤ) → sum8ℤ v ≡ 0ℤ → Vec8Eq (K8LaplacianVec8ℤ v) (eightVec8ℤ v)
law14G-16-sum0-eigen8 v sum0 =
 ( λ i →
    trans
     (cong (λ s → eightTimesℤ (left4 v i) +ℤ negℤ s) sum0)
     (+ℤ-zero-right (eightTimesℤ (left4 v i)))
 ) ,
 ( λ i →
    trans
     (cong (λ s → eightTimesℤ (right4 v i) +ℤ negℤ s) sum0)
     (+ℤ-zero-right (eightTimesℤ (right4 v i)))
 )
```

Law 14G.17: Pointwise 8-Eigen Forces Sum-Zero

If $L_8\, v = 8 \cdot v$ pointwise, then at the first coordinate $8 \cdot v_0 - \Sigma_8\, v = 8 \cdot v_0$. Cancelling the common term leaves $-\Sigma_8\, v = 0$, so the 8-eigenspace is exactly the sum-zero subspace.

```
– § L₈ v = 8·v => Σ₈ v = 0
law14G-17-eigen8→sum0 : (v : Vec8ℤ) → Vec8Eq (K8LaplacianVec8ℤ v) (eightVec8ℤ v) → sum8ℤ v ≡ 0ℤ
law14G-17-eigen8→sum0 v eigen8 =
 let a = eightTimesℤ (left4 v g0) in
 let s = sum8ℤ v in
 let eq₀ : a +ℤ negℤ s ≡ a
     eq₀ = fst eigen8 g0
 in
 negℤ-zero→zero s (+ℤ-cancel-left a (negℤ s) eq₀)
```

Law 14G.18: Biconditional Sum-Zero ⇔ 8-Eigen

Law 14G.16 and Law 14G.17 prove both directions of the equivalence between sum-zero and 8-eigen. The two predicates are packaged as one biconditional.

```
– § sum0 ↔ eigen8 (both directions)
law14G-18-sum0→eigen8 : (v : Vec8ℤ) → sum8ℤ v ≡ 0ℤ → Vec8Eq (K8LaplacianVec8ℤ v) (eightVec8ℤ v)
law14G-18-sum0→eigen8 = law14G-16-sum0-eigen8

law14G-18-eigen8→sum0 : (v : Vec8ℤ) → Vec8Eq (K8LaplacianVec8ℤ v) (eightVec8ℤ v) → sum8ℤ v ≡ 0ℤ
law14G-18-eigen8→sum0 = law14G-17-eigen8→sum0
```

Law 14G.19: Constants Are Forced 0-Eigenvectors

A constant vector with value x has total sum $8{\cdot}x$, and each coordinate of L_8 becomes $8{\cdot}x - 8{\cdot}x = 0$. The constant subspace therefore survives exactly as the 0-eigenspace.

```
-- § constant vectors lie in kernel of L₈
law14G-19-const-eigen0 : (x : ℤ) → Vec8Eq (K8LaplacianVec8ℤ (constVec8ℤ x)) zeroVec8ℤ
law14G-19-const-eigen0 x =

       (trans
        (cong (λ t → fourTimesℤ x +ℤ t) (sumFin4-const x))
        refl)
 in
 ( λ _ →
     trans
      (cong (λ s → eightTimesℤ x +ℤ negℤ s) sc)
      (+ℤ-inv-right (eightTimesℤ x))
 ) ,
 ( λ _ →
     trans
      (cong (λ s → eightTimesℤ x +ℤ negℤ s) sc)
      (+ℤ-inv-right (eightTimesℤ x))
 )
```

Law 14G.20: Kernel Condition $L_8\, v = 0 \Leftrightarrow 8 \cdot v = J_8\, v$

The kernel equation at each coordinate reads $8 \cdot v_i - \Sigma_8\, v = 0$. Moving the sum term across the equality forces $8 \cdot v_i = \Sigma_8\, v$, which is precisely the broadcast equation $8 \cdot v = J_8\, v$. Kernel membership is thus classified without residue.

Laws 14G.21–14G.22: Image Characterization

The image of L_8 is obtained by applying L_8 once, so Law 14G.15 applies immediately and pins every image vector to the 8-eigenspace. Law 14G.16 then confirms that every sum-zero vector supplies an explicit preimage after 8-scaling—the image and the 8-eigenspace coincide.

```
-- § image vectors are 8-eigenvectors
law14G-21-image⊆eigen8 : (v : Vec8ℤ) → Vec8Eq (K8LaplacianVec8ℤ (K8LaplacianVec8ℤ v)) (eightVec8ℤ (K8LaplacianVec8ℤ v))
law14G-21-image⊆eigen8 = law14G-15-LL-eightL

-- § sum-zero vectors become image vectors after 8-scaling

law14G-22-sum0→eightInImage w sum0 = w , law14G-16-sum0-eigen8 w sum0
```

Transport Lemmas

Pointwise equality must propagate through sums, scaling, and the K_8 Laplacian without book-keeping ambiguity. Each lemma below fixes exactly one transport path.

Constraint: Without explicit congruence laws for sumFin4ℤ, sum8ℤ, eightVec8ℤ, and K_8L, equational rewriting along Vec8Eq would fail to close in Agda even when the underlying mathematics is trivial.

Construction: Vec8Eq-refl/sym/trans, sumFin4-cong, sum8-cong, eightVec8-cong, and K_8Laplacian-cong are built component-wise from cong, sym, trans, and the already-forced Σ_4 congruence.

Consequence: Pointwise equality propagates through every K_8 operator without ambiguity, so the spectral package can be transported to the survivor dispatch in the next section.

Full Survivor: Forced Spectral Consequences

The already-forced K_8 spectral laws transfer directly to the full survivor.

Constraint: Once Law 14G.8 identifies the full-survivor Laplacian with L_8 pointwise, every spectral law about L_8 must transport to the dispatched form; failing to package this transport would force downstream consumers to repeat the same proofs.

Construction: The transport is performed by the existing Vec8Eq congruence lemmas applied to Laws 14G.12–14G.22, packaging the global-sum law, the operator annihilations, and the spectral biconditional under the dispatcher laplacianSurvivorVec8ℤ survivor-full.

Consequence: The full survivor inherits the complete K_8 spectral package without reproving any identity; the empty survivor inherits its block-diagonal spectrum from L_4 in the same way. Law 14G.8 eliminates any distinction between the full survivor Laplacian and L_8, so every remaining consequence is forced by transport.

Law 14G.23: $\Sigma_8(L_{\text{full}}\, v) = 0$

The full survivor coincides pointwise with L_8 by Law 14G.8, so the sum computation reduces to Law 14G.12 directly—the full-survivor image is forced into the sum-zero subspace.

```
-- § global sum of the full-survivor Laplacian is 0
law14G-23-sumL-survivor-full-0 : (v : Vec8ℤ) → sum8ℤ (laplacianSurvivorVec8ℤ survivor-full v) ≡ 0ℤ
law14G-23-sumL-survivor-full-0 v =
 trans
  (sum8-cong (laplacianSurvivorVec8ℤ survivor-full v) (K8LaplacianVec8ℤ v) (law14G-8-survivor-full-K8 v))
  (law14G-12-sumL8-0 v)
```

Law 14G.24: $J_8(L_{\text{full}}\, v) = 0$

Because J_8 broadcasts the global sum of its input and Law 14G.23 forces that sum to vanish, J_8 annihilates every vector in the full-survivor image.

```
-- § J₈ annihilates full-survivor image
law14G-24-JL-survivor-full-zero : (v : Vec8ℤ) → Vec8Eq (J8Vec8ℤ (laplacianSurvivorVec8ℤ survivor-full v)) zeroVec8ℤ
law14G-24-JL-survivor-full-zero v =
 let sum0 = law14G-23-sumL-survivor-full-0 v in
 (λ _ → sum0) , (λ _ → sum0)
```

Laws 14G.25–14G.26: Sum-Zero ⇔ 8-Eigen for Full Survivor

Under Law 14G.8 the full survivor is L_8, so Law 14G.16 and Law 14G.17 transfer across that identification without adding new cases. Sum-zero and 8-eigen remain the unique surviving conditions.

```
– § sum-zero → 8-eigenvector for full survivor
law14G-25-survivor-full-sum0→eigen8 : (v : Vec8ℤ) → sum8ℤ v ≡ 0ℤ → Vec8Eq (laplacianSurvivorVec8ℤ survivor-full v) (eightVec8ℤ v)
law14G-25-survivor-full-sum0→eigen8 v sum0 =

– § 8-eigenvector → sum-zero for full survivor
law14G-26-survivor-full-eigen8→sum0 : (v : Vec8ℤ) → Vec8Eq (laplacianSurvivorVec8ℤ survivor-full v) (eightVec8ℤ v) → sum8ℤ v ≡ 0ℤ
law14G-26-survivor-full-eigen8→sum0 v eigen8 =
 law14G-17-eigen8→sum0 v
  (Vec8Eq-trans
   (Vec8Eq-sym (law14G-8-survivor-full-K8 v))
   eigen8)
```

Empty Survivor: Forced Block Spectral Consequences

The empty survivor reduces to two independent K_4 blocks. Block diagonality eliminates every cross-term, so the surviving spectral laws are forced blockwise from the earlier K_4 development.

Law 14G.27: $\Sigma_8(L_{\text{empty}}\, v) = 0$

Block diagonality splits the total sum of the empty survivor into the left and right K_4 Laplacian sums. Law 14E.28 forces each block sum to vanish independently, so the empty-survivor image lies in the global sum-zero subspace.

```
– § global sum of empty-survivor Laplacian is 0
law14G-27-sumL-survivor-empty-0 : (v : Vec8ℤ) → sum8ℤ (laplacianSurvivorVec8ℤ survivor-empty v) ≡ 0ℤ
law14G-27-sumL-survivor-empty-0 v =
 trans
  (cong (λ t → t +ℤ sumFin4ℤ (laplacianVec4ℤ (right4 v))) (law14E-28-sumLaplacian0 (left4 v)))
  (trans
   (cong (λ t → 0ℤ +ℤ t) (law14E-28-sumLaplacian0 (right4 v)))
   (+ℤ-zero-left 0ℤ))
```

Law 14G.28: $J_8(L_{\text{empty}}\, v) = 0$

Since J_8 depends only on the global sum of its input and Law 14G.27 eliminates that sum, the empty-survivor image is annihilated by J_8.

```
– § J₈ annihilates empty-survivor image
law14G-28-JL-survivor-empty-zero : (v : Vec8ℤ) → Vec8Eq (J8Vec8ℤ (laplacianSurvivorVec8ℤ survivor-empty v)) zeroVec8ℤ
law14G-28-JL-survivor-empty-zero v =
 let sum0 = law14G-27-sumL-survivor-empty-0 v in
 (λ _ → sum0) , (λ _ → sum0)
```

Laws 14G.29–14G.30: Blockwise Sum-Zero ⇔ 4-Eigen for Empty Survivor

The empty survivor acts as two independent K_4 Laplacians. Law 14E.11 and Law 14E.19 classify each block separately, leaving no mixed alternative—blockwise sum-zero and pointwise 4-eigen are the unique surviving conditions.

```
– § blockwise sum-zero → pointwise 4-eigenvector for empty survivor
law14G-29-survivor-empty-sum0→eigen4 : (v : Vec8ℤ) → sumFin4ℤ (left4 v) ≡ 0ℤ → sumFin4ℤ (right4 v) ≡ 0ℤ →
 Vec8Eq (laplacianSurvivorVec8ℤ survivor-empty v) (fourVec8ℤ v)
law14G-29-survivor-empty-sum0→eigen4 v sum0L sum0R =
 ( λ i → law14E-11-sum0-eigen4 (left4 v) i sum0L ) ,
 ( λ i → law14E-11-sum0-eigen4 (right4 v) i sum0R )

– § pointwise 4-eigen → blockwise sum-zero for empty survivor
law14G-30-survivor-empty-eigen4→sum0 : (v : Vec8ℤ) → Vec8Eq (laplacianSurvivorVec8ℤ survivor-empty v) (fourVec8ℤ v) →
 (sumFin4ℤ (left4 v) ≡ 0ℤ) × (sumFin4ℤ (right4 v) ≡ 0ℤ)
law14G-30-survivor-empty-eigen4→sum0 v eigen4 =
 law14E-19-eigen4→sum0 (left4 v) (fst eigen4) ,
 law14E-19-eigen4→sum0 (right4 v) (snd eigen4)
```

Law 14G.31: Split Constants Are 0-Eigenvectors of the Empty Survivor

On each block, a constant vector is already a forced 0-eigenvector of the K_4 Laplacian. Block diagonality prevents the two constants from interacting across blocks, so split constants survive exactly as kernel witnesses for the empty survivor.

```
– § split constant vector
constVec8Splitℤ : ℤ → ℤ → Vec8ℤ
constVec8Splitℤ x y = constVec4ℤ x , constVec4ℤ y

– § split constants lie in kernel of empty survivor
law14G-31-splitConst-eigen0-empty : (x y : ℤ) → Vec8Eq (laplacianSurvivorVec8ℤ survivor-empty (constVec8Splitℤ x y)) zeroVec8ℤ
law14G-31-splitConst-eigen0-empty x y =
 ( λ i → law14E-13-const-eigen0 x i ) ,
 ( λ i → law14E-13-const-eigen0 y i )
```

Law 14G.32: Empty Survivor Image is 4-Eigen

Applying the empty survivor twice applies each K_4 Laplacian twice on its own block. Law 14E.29 collapses each repeated block action to 4 times the first image, forcing every vector in the empty-survivor image into the 4-eigenspace.

```
– § image of empty survivor ⊆ 4-eigenspace
law14G-32-imageEmpty⊆eigen4 : (v : Vec8ℤ) →
 Vec8Eq (laplacianSurvivorVec8ℤ survivor-empty (laplacianSurvivorVec8ℤ survivor-empty v))
  (fourVec8ℤ (laplacianSurvivorVec8ℤ survivor-empty v))
law14G-32-imageEmpty⊆eigen4 v =
 ( λ i → law14E-29-LL-fourL (left4 v) i ) ,
 ( λ i → law14E-29-LL-fourL (right4 v) i )
```

Law 14G.33: Sum-Zero ⇒ Image Witness After 4-Scaling

Law 14G.29 already forces a blockwise sum-zero vector to satisfy the empty-survivor eigenvalue equation. Choosing the vector itself as preimage eliminates any search for an additional witness—every blockwise sum-zero vector has an explicit image witness after 4-scaling.

```
– § blockwise sum-zero → 4·v is in the image
law14G-33-sum0→fourInImage-empty : (v : Vec8ℤ) → sumFin4ℤ (left4 v) ≡ 0ℤ → sumFin4ℤ (right4 v) ≡ 0ℤ →
 Σ Vec8ℤ (λ w → Vec8Eq (laplacianSurvivorVec8ℤ survivor-empty w) (fourVec8ℤ v))
law14G-33-sum0→fourInImage-empty v sum0L sum0R = v , law14G-29-survivor-empty-sum0→eigen4 v sum0L sum0R
```

Full Survivor Image Law

The image law for the full survivor is a direct transport consequence. No new spectral case appears here; Law 14G.15 is merely re-expressed through the survivor identification.

Law 14G.34: Full Survivor Image ⊆ 8-Eigenspace

The full survivor is identified with L_8 both before and after one further application, so the claim reduces to Law 14G.15 by transport on both sides. Scaling congruence carries the codomain back, forcing the full-survivor image into the 8-eigenspace.

```
– § full survivor image vectors are 8-eigenvectors
law14G-34-survivor-full-image⊆eigen8 : (v : Vec8ℤ) →
 Vec8Eq (laplacianSurvivorVec8ℤ survivor-full (laplacianSurvivorVec8ℤ survivor-full v))
     (eightVec8ℤ (laplacianSurvivorVec8ℤ survivor-full v))
law14G-34-survivor-full-image⊆eigen8 v =
 let eqV : Vec8Eq (laplacianSurvivorVec8ℤ survivor-full v) (K8LaplacianVec8ℤ v)
     eqV = law14G-8-survivor-full-K8 v
     eqLL : Vec8Eq (laplacianSurvivorVec8ℤ survivor-full (laplacianSurvivorVec8ℤ survivor-full v))
            (K8LaplacianVec8ℤ (laplacianSurvivorVec8ℤ survivor-full v))
     eqLL = law14G-8-survivor-full-K8 (laplacianSurvivorVec8ℤ survivor-full v)
     step₁ : Vec8Eq (laplacianSurvivorVec8ℤ survivor-full (laplacianSurvivorVec8ℤ survivor-full v))
                    (K8LaplacianVec8ℤ (K8LaplacianVec8ℤ v))
     step₁ =
      Vec8Eq-trans
       eqLL
       (K8Laplacian-cong (laplacianSurvivorVec8ℤ survivor-full v) (K8LaplacianVec8ℤ v) eqV)
     step₂ : Vec8Eq (K8LaplacianVec8ℤ (K8LaplacianVec8ℤ v)) (eightVec8ℤ (K8LaplacianVec8ℤ v))
     step₂ = law14G-15-LL-eightL v
     step₃ : Vec8Eq (eightVec8ℤ (K8LaplacianVec8ℤ v)) (eightVec8ℤ (laplacianSurvivorVec8ℤ survivor-full v))
     step₃ = Vec8Eq-sym (eightVec8-cong (laplacianSurvivorVec8ℤ survivor-full v) (K8LaplacianVec8ℤ v) eqV)
 in
 Vec8Eq-trans step₁ (Vec8Eq-trans step₂ step₃)
```

Survivor Spectral Packages

Packaging the already-forced survivor consequences into reusable witnesses adds no new ontology—it only collects the eliminated cases into a single typed interface.

Law 14G.35: Full Survivor Spectral Package

Law 14G.23, Law 14G.24, Laws 14G.25–14G.26, and Law 14G.34 already force all full-survivor spectral data. Product formation collects those forced components without introducing any new branch, yielding a single composite spectral witness.

```
– § full survivor spectral package
law14G-35-survivor-full-spectral-package : (v : Vec8ℤ) →
 (sum8ℤ (laplacianSurvivorVec8ℤ survivor-full v) ≡ 0ℤ) ×
 (Vec8Eq (J8Vec8ℤ (laplacianSurvivorVec8ℤ survivor-full v)) zeroVec8ℤ) ×
 ((sum8ℤ v ≡ 0ℤ → Vec8Eq (laplacianSurvivorVec8ℤ survivor-full v) (eightVec8ℤ v)) ×
  (Vec8Eq (laplacianSurvivorVec8ℤ survivor-full v) (eightVec8ℤ v) → sum8ℤ v ≡ 0ℤ)) ×
 (Vec8Eq (laplacianSurvivorVec8ℤ survivor-full (laplacianSurvivorVec8ℤ survivor-full v))
  (eightVec8ℤ (laplacianSurvivorVec8ℤ survivor-full v)))
law14G-35-survivor-full-spectral-package v =
 law14G-23-sumL-survivor-full-0 v ,
 (law14G-24-JL-survivor-full-zero v ,
  ((law14G-25-survivor-full-sum0→eigen8 v , law14G-26-survivor-full-eigen8→sum0 v) ,
   law14G-34-survivor-full-image⊆eigen8 v))
```

Law 14G.36: Empty Survivor Spectral Package

Law 14G.27 through Law 14G.32 already force the empty-survivor spectral data. The blockwise consequences and kernel witnesses are collected as one product—a single composite spectral witness for the empty survivor.

```
– § empty survivor spectral package
law14G-36-survivor-empty-spectral-package : (v : Vec8ℤ) →
 (sum8ℤ (laplacianSurvivorVec8ℤ survivor-empty v) ≡ 0ℤ) ×
 (Vec8Eq (J8Vec8ℤ (laplacianSurvivorVec8ℤ survivor-empty v)) zeroVec8ℤ) ×
 ((sumFin4ℤ (left4 v) ≡ 0ℤ → sumFin4ℤ (right4 v) ≡ 0ℤ → Vec8Eq (laplacianSurvivorVec8ℤ survivor-empty v) (fourVec8ℤ v)) ×
  (Vec8Eq (laplacianSurvivorVec8ℤ survivor-empty v) (fourVec8ℤ v) → (sumFin4ℤ (left4 v) ≡ 0ℤ) × (sumFin4ℤ (right4 v) ≡ 0ℤ))) ×
 ((x y : ℤ) → Vec8Eq (laplacianSurvivorVec8ℤ survivor-empty (constVec8Splitℤ x y)) zeroVec8ℤ) ×
 (Vec8Eq (laplacianSurvivorVec8ℤ survivor-empty (laplacianSurvivorVec8ℤ survivor-empty v))
  (fourVec8ℤ (laplacianSurvivorVec8ℤ survivor-empty v)))
law14G-36-survivor-empty-spectral-package v =
 law14G-27-sumL-survivor-empty-0 v ,
 (law14G-28-JL-survivor-empty-zero v ,
  ((law14G-29-survivor-empty-sum0→eigen4 v , law14G-30-survivor-empty-eigen4→sum0 v) ,
   (law14G-31-splitConst-eigen0-empty ,
    law14G-32-imageEmpty⊆eigen4 v)))
```

Law 14G.37: Spectral Package by Forced Case Split

The survivor type has exactly two constructors by Law 14G.6. Exhaustive case split eliminates every index except survivor-empty and survivor-full, forcing a uniform survivor-indexed spectral package for every case.

```
– § type-level spectral package indexed by survivor
SurvivorSpectralPackage : CouplingSurvivor → Vec8ℤ → Set
SurvivorSpectralPackage survivor-full v =
 (sum8ℤ (laplacianSurvivorVec8ℤ survivor-full v) ≡ 0ℤ) ×
 (Vec8Eq (J8Vec8ℤ (laplacianSurvivorVec8ℤ survivor-full v)) zeroVec8ℤ) ×
 ((sum8ℤ v ≡ 0ℤ → Vec8Eq (laplacianSurvivorVec8ℤ survivor-full v) (eightVec8ℤ v)) ×
```

```
  (Vec8Eq (laplacianSurvivorVec8ℤ survivor-full v) (eightVec8ℤ v) → sum8ℤ v ≡ 0ℤ)) ×
 (Vec8Eq (laplacianSurvivorVec8ℤ survivor-full (laplacianSurvivorVec8ℤ survivor-full v))
  (eightVec8ℤ (laplacianSurvivorVec8ℤ survivor-full v)))
SurvivorSpectralPackage survivor-empty v =
 (sum8ℤ (laplacianSurvivorVec8ℤ survivor-empty v) ≡ 0ℤ) ×
 (Vec8Eq (J8Vec8ℤ (laplacianSurvivorVec8ℤ survivor-empty v)) zeroVec8ℤ) ×
 ((sumFin4ℤ (left4 v) ≡ 0ℤ → sumFin4ℤ (right4 v) ≡ 0ℤ → Vec8Eq (laplacianSurvivorVec8ℤ survivor-empty v) (fourVec8ℤ v)) ×
  (Vec8Eq (laplacianSurvivorVec8ℤ survivor-empty v) (fourVec8ℤ v) → (sumFin4ℤ (left4 v) ≡ 0ℤ) × (sumFin4ℤ (right4 v) ≡ 0ℤ))) ×
 ((x y : ℤ) → Vec8Eq (laplacianSurvivorVec8ℤ survivor-empty (constVec8Splitℤ x y)) zeroVec8ℤ) ×
 (Vec8Eq (laplacianSurvivorVec8ℤ survivor-empty (laplacianSurvivorVec8ℤ survivor-empty v))
  (fourVec8ℤ (laplacianSurvivorVec8ℤ survivor-empty v)))

-- § forced case-split over survivor constructors

Chapter 34

Triple K_4 Laplacian

The two-copy coupled Laplacian of the previous chapter forced a binary classification: full join or disjoint union, with eigenvalue 8 governing the spectral theory. Three copies force the same elimination again, now under the copy symmetry of S_3 and the endomorphism symmetries on each K_4 factor. These constraints eliminate every intermediate coupling, force the same binary survivors, and then force the 12-vertex operator algebra and its spectral packages.

Copy_3 Infrastructure

Three copies, decidable equality for each pair, and the full symmetric group S_3 are forced as the minimal copy infrastructure. Representation freedom collapses once the copy type, its equality test, and the six explicit bijections that exhaust the copy symmetries are fixed.

Constraint: Without a fixed three-element type, decidable copy equality, and an explicit enumeration of all six S_3 bijections, every later coupling proof would branch on alternative copy presentations and the K_{12} symmetry chain would lose its closed form.

Construction: The data type $\mathrm{Copy3}$ fixes the three indistinguishable copies; pairwise inequality witnesses and a 9-case decidable equality close the equality structure; the six $\mathrm{CopyPerm}$ witnesses (permId_3, three transpositions, two cycles) exhaust S_3 explicitly.

Consequence: Every later three-copy proof speaks one canonical copy language. The cardinality $|S_3| = 6$ is invariant under $\mathrm{Aut}(K_4)$; any deviation would break the symmetry chain and is therefore a necessary observable.

```

Copy Transport and Cross-Coupling

The transport laws for three-copy couplings are fixed here. The four-argument transport and the exhaustive 6×6 pair table eliminate all freedom in moving witnesses between ordered distinct copy pairs.

Constraint: A coupling witness at one ordered distinct pair (c_0, d_0) must transport to every other ordered distinct pair (c, d), otherwise the cross-coupling dichotomy would split into thirty disjoint cases and the single-edge-forces-all law could not be stated.

Elimination: The 36-row $\mathrm{sendPair}_3$ table eliminates every coincident pair via $\bot$-elim on the inequality witnesses, and assigns to every ordered distinct pair a unique permutation that maps (c_0, d_0) onto (c, d). No row is left unmatched; no alternative witness survives.

Consequence: The pair-orbit of S_3 on ordered distinct pairs is transitive. Coupling witnesses transport without ambiguity; the next section's join law has a single hypothesis-form.

```
-- § transport across four arguments (copies + endpoints)
transport4 : {C : Copy3 → Copy3 → EndoCase → EndoCase → Set}
 {c c' d d' : Copy3} {a a' b b' : EndoCase} →

Vec$_{12}$ Infrastructure

A 12-vertex vector is three blocks of four, with block projections, pointwise equality, and the global-sum and all-ones operators. Representation freedom is eliminated by fixing the unique block decomposition on which all later K_{12} laws are forced.

Constraint: The three-copy carrier $\mathrm{Fin}_4 \times \mathrm{Copy}_3$ admits exactly one decomposition into three Vec4$\mathbb{Z}$ blocks; any other encoding would either lose block-wise projections or duplicate the Σ_{12} definition.

Construction: $\mathrm{Vec12}\mathbb{Z} = \mathrm{Vec4}\mathbb{Z} \times (\mathrm{Vec4}\mathbb{Z} \times \mathrm{Vec4}\mathbb{Z})$ with projections $\mathrm{block}_0, \mathrm{block}_1, \mathrm{block}_2$, pointwise equality Vec12Eq, Σ_{12} as the sum of the three block sums, the all-ones broadcast J_{12}, the scalar $\mathrm{twelveTimes}\mathbb{Z}\, x = \mathrm{fourTimes}\mathbb{Z}\, x + \mathbb{Z}\mathrm{eightTimes}\mathbb{Z}\, x$, and the opaque K_{12} Laplacian $\mathrm{twelveTimes}\mathbb{Z} v_i + \mathbb{Z}\mathrm{neg}\mathbb{Z}\, (\Sigma_{12} v)$.

Consequence: Block-wise transport is forced; the empty coupling collapses to $L_4 \oplus L_4 \oplus L_4$ and the full coupling is forced to coincide with $K_{12} L$.

Survivor Dispatch and Vec_{12} Operations

The two survivor actions on Vec_{12} and the operations required to compare them are fixed here. The block-diagonal form, the full K_{12} form, and the binary survivor dispatch fix every remaining implementation choice before the spectral laws begin.

Constraint: The triple-coupling classification (Laws 14H.0–14H.1) leaves exactly two survivor kinds; the dispatcher and the auxiliary Vec12ℤ operations must be defined now, before the spectral package is assembled, or the later proofs cannot be stated.

Construction: Laws 14H.2–14H.4 verify the two survivor identifications and the binary case split by (λ_ → refl). The dispatcher laplacianSurvivorVec12ℤ pattern-matches the two constructors, and the addition, negation, scalar twelveVec12ℤ, constant, and zero vectors are defined block-wise from the Vec4ℤ counterparts. Two refl lemmas pin Σ_{12} on constants and on $J_{12}v$.

Consequence: No third dispatch branch survives, and the spectral chapter can quote a single dispatcher symbol for both survivor kinds.

```

K_{12} Operator Algebra

Once L_{12} is fixed as $12I - J_{12}$, the operator algebra is forced. The identities $J^2 = 12J$, $L + J = 12I$, and the remaining operator equalities follow without further branching.

Constraint: The two-operator identity $L_{12} + J_{12} = 12I$ is the only relation that is consistent with $L_{12}\, v_i = 12v_i - \Sigma_{12} v$ and $J_{12}\, v_i = \Sigma_{12} v$ at every coordinate; relaxing it would break the global-sum collapse in the next section.

Construction: Law 14H.5 proves $J_{12}^2 = 12J_{12}$ by a single sum12-J_{12} application per block; Law 14H.6 (and following) close $L_{12} + J_{12} = 12I$ by per-block equational chains using $+\mathbb{Z}$-assoc, $+\mathbb{Z}$-inv-left, and the opaque unfolding of $K_{12}L$.

Consequence: Operator algebra on L_{12} and J_{12} reduces to refl-terminated chains and the spectral classification can use these identities as black-box rewrites.

```
-- § Law 14H.5: J₁₂² = 12·J₁₂
law14H-5-JJ-twelveJ : (v : Vec12ℤ) → Vec12Eq (J12Vec12ℤ (J12Vec12ℤ v)) (twelveVec12ℤ (J12Vec12ℤ v))
law14H-5-JJ-twelveJ v =
 (λ _ → sum12-J12 v) ,
 ((λ _ → sum12-J12 v) ,
  (λ _ → sum12-J12 v))
```

Laplacian operator identities. With $J^2 = 12J$ established, the remaining operator identities require unfolding the opaque Laplacian definition. The decomposition $12v = Lv + Jv$, scalar distributivity of $12\times$, and the sum–Laplacian commutation all follow inside a single opaque scope.

K_{12} Operator Annihilation

The forced relations $J_{12} \circ L_{12} = 0$, $L_{12} \circ J_{12} = 0$, and $L_{12}^2 = 12 \cdot L_{12}$ are proven here. Once Law 14H.8 pins the total sum of $L_{12}v$ to zero, both mixed composites collapse to the zero operator and the double Laplacian collapses to $12 \cdot L_{12}$.

Constraint: If $\Sigma_{12}(L_{12}v) = 0$ failed on any vector, then $J_{12} \circ L_{12}$ would carry a residual broadcast and the minimal polynomial of L_{12} would no longer factor as $X(X - 12)$.

Construction: Law 14H.9 reads $J_{12}(L_{12}v)$ block-wise as $\Sigma_{12}(L_{12}v)$ and substitutes Law 14H.8 to land at $0_{\mathbb{Z}}$; Law 14H.10 reads $L_{12}(J_{12}v)$ as $12\Sigma_{12}v - \Sigma_{12}(J_{12}v)$ and closes via sum12-J_{12} and $+\mathbb{Z}$-inv-right; Law 14H.11 expands $L_{12}^2 v$ and substitutes Law 14H.8 inside the neg$\mathbb{Z}$ to land at $12 \cdot L_{12}v$.

Consequence: The operator annihilation package is forced and the spectral classification in the next section can treat both composites as zero rewrites.

K_{12} Spectral Classification

The spectrum of L_{12} is classified completely. Sum-zero forces the 12-eigenspace, constants force the kernel, and the image is forced into the same eigen-constraint by the operator laws.

Constraint: A spectrum left undecided between sum-zero and the 12-eigenspace would let two distinct invariant subspaces share the same image, breaking the kernel/image complementarity that the K_{12} operator algebra demands.

Construction: Laws 14H.12–14H.17 prove the four directions $\Sigma_{12}v = 0 \Rightarrow L_{12}v = 12v$, $L_{12}v = 12v \Rightarrow \Sigma_{12}v = 0$, $L_{12}(\text{const}\, x) = 0$, $L_{12}v = 0 \Leftrightarrow 12v = J_{12}v$, and the image-preimage witness, all by per-block equational chains using $+\mathbb{Z}$-zero-right, $+\mathbb{Z}$-cancel-left, neg$\mathbb{Z}$-zero- $\rightarrow$ -zero, $+\mathbb{Z}$-inv-left, and $+\mathbb{Z}$-assoc.

Consequence: The two eigenspaces are completely classified and the image lies inside the 12-eigenspace; nothing weaker than this biconditional survives.

Full Survivor Spectral Package

The forced spectral consequences of the full three-copy survivor are packaged here. The package introduces no new structure; it only collects the already-classified cases into a single witness type for downstream transport.

Constraint: Downstream consumers of the K_{12} chapter need a single record-shaped witness that bundles the global-sum law, the operator-annihilation laws, and the spectral biconditional; without the package the same five proofs would have to be re-quoted at every call site.

Construction: Survivor3FullSpectralPackage v is a Σ-record of the four pieces forced above; Law 14H.18 inhabits it by tupling Laws 14H.8, 14H.9, 14H.12, 14H.13, and 14H.16 directly.

Consequence: The full-survivor spectrum is delivered as one term; the empty survivor inherits its block-diagonal package from the three L_4 instances in the same way.

```
-- § full-survivor spectral package type

Spectrum Rigidity: Eigen-Residue is Pinned to $\Sigma_{12}v$

The operator identities of the previous sections settle $L_{12}^2 = 12L_{12}$, $J_{12}^2 = 12J_{12}$, $L_{12}J_{12} = J_{12}L_{12} = 0$, and the kernel/image equivalences. They do not yet decide what integer eigenvalues L_{12} admits on arbitrary $v \in \mathrm{Vec12}_{\mathbb{Z}}$. The rigidity theorem below pins it down: at every entry of every block, the difference $12 \cdot v_i - (L_{12}v)_i$ collapses to the single integer $\Sigma_{12}v$. Two entries with distinct candidate eigen-values are therefore impossible—the residue is constant across the entire 12-vertex carrier.

Constraint: If two block-entries gave different residues $12 \cdot v_i - (L_{12}v)_i$, the candidate eigen-action would have to assume two different values that the global identity $L_{12} = 12I - J_{12}$ forbids. The operator algebra would split.

Construction: The pin equation $12 \cdot v_i + (-(L_{12}v)_i) \equiv \Sigma_{12}v$ is forced inside the opaque unfolding by the chain $t+(-(t+(-s))) \equiv s$ via `neg-+ℤ`, `negℤ-involutive`, `+ℤ-assoc`, `+ℤ-inv-right`, `+ℤ-zero-left`. The cross-block equality is transitivity through $\Sigma_{12}v$.

Consequence: Any integer eigen-action $e_k : \mathrm{Fin4} \to \mathbb{Z}$ satisfying $L_{12}v = e$ pointwise must obey $12 \cdot v_{k,i} - e_k(i) = \Sigma_{12}v$ at every (k, i). Specialising to the linear case $e_k(i) = \lambda \cdot v_{k,i}$, two entries with $v_{k_1,i_1} \neq v_{k_2,i_2}$ force $(12-\lambda)\cdot(v_{k_1,i_1} - v_{k_2,i_2}) = 0$, which over $\mathbb{Z}$ leaves $\lambda \in \{0, 12\}$ as the only integer eigenvalues. The 0, 12-dichotomy is now a corollary, not an assertion.

The spectral theory of the coupled and triple K_4 Laplacians yields the operator identities $L^2 = 12L$, $J^2 = 12J$, $LJ = JL = 0$ on $\mathrm{Vec12}_{\mathbb{Z}}$ (Laws 14H.5, 14H.9–14H.11), the kernel/image equivalences (Laws 14H.12–14H.16), and now the spectrum-rigidity theorem 14H.19–14H.21: the eigen-residue is pinned to $\Sigma_{12}v$ at every entry, and any candidate eigen-action is determined globally rather than per index.

The spectral data is exact within the laws as stated. The arithmetic on which it rests—$\mathbb{Z}$ and $\mathbb{Q}$—requires order and distance infrastructure for convergence arguments: additive order monotonicity, rational multiplication, ε-splitting, and distance laws. These are forced algebraic consequences of the integer and rational definitions already established. With those laws in place, the spectral data has a metric home and the passage to the reals is forced by the Cauchy gaps rational arithmetic cannot close internally.

Chapter 35

Additive Order Laws for $\leq_{\mathbb{Q}}$

Cauchy convergence arguments require combining two distance bounds into one: if $|x_m - x_n| < \varepsilon/2$ and $|x_n - x_k| < \varepsilon/2$, then $|x_m - x_k| < \varepsilon$. This chapter establishes the additive monotonicity and sum-doubling laws for the rational order. Nonnegative rationals must remain closed under addition, and each order comparison must be stable under adding the same quantity on either side. These constraints force the additive order toolkit used later in the Cauchy arguments.

Nonnegativity Extraction and Closure

Nonnegativity must survive passage from rationals to numerators and back through addition. The reduction always collapses to integer nonnegativity after clearing denominators.

Constraint: If nonnegativity did not pass cleanly between $\mathbb{Q}_{\geq 0}$ and $\mathbb{Z}_{\geq 0}$ via cross-multiplication by the positive denominator, the rational order would acquire a sign-defect that no later metric estimate could repair.

Construction: $0{\leq}\mathbb{Z}$-from$\mathbb{N}\mathbb{Z}$ forges nonnegativity for every from$\mathbb{N}\mathbb{Z}\,n$; $0{\leq}\mathbb{Q}{\to}0{\leq}\mathbb{Z}$num extracts integer nonnegativity from the rational witness via the $a \cdot 1 = a$ collapse; $0{\leq}\mathbb{Q}$-$+\mathbb{Q}$ composes both bounds into nonneg-closure of $+_{\mathbb{Q}}$.

Consequence: Rational nonnegativity is closed under addition and reflects to integer nonnegativity on the numerator. Every later order estimate may reduce to integer arithmetic without losing sign information.

Sum-Doubling Bounds

If $0 \leq x, y, z$ with $x \leq z$ and $y \leq z$, then $x + y \leq z + z$. The integer version lifts through the natural-number representation, and the rational version is forced by the same bound after scaling to a common denominator.

Constraint: Without a doubling bound on bounded sums, the $\varepsilon/2$-splitting of the next chapter would lack its core arithmetic step and the triangle estimate would not close.

Construction: The integer sum-doubling lifts each $x, y, z \geq 0$ through $0{\leq}\mathbb{Z}{\to}\mathrm{from}\mathbb{N}\mathbb{Z}$ into natural-number representatives, applies $m \leq k \wedge n \leq k \Rightarrow m + n \leq k + k$, then transports back. The rational version applies the integer bound after clearing denominators by the common scale.

Consequence: Bounded sums double cleanly in $\mathbb{Z}$ and $\mathbb{Q}$. The arithmetic backbone of the ε-splitting and triangle estimates is forced.

Nonneg-Right Addition and Monotonicity

Adding a nonnegative term on the right preserves the order; this extends to full left and right monotonicity of rational addition. Directional ambiguity is eliminated by forcing right-monotonicity first and then transporting left-monotonicity through commutativity.

Constraint: Without right-monotonicity of addition, every later ε-bound chain would split between left- and right-additive estimates and the rational order would lose its single canonical congruence.

Construction: neg≤normalize forges the negative-side base case; ≤ℤ-add-pos-right adds positive integers without changing direction; the rational lifts ≤ℚ-+ℚ-mono^r and the commutativity-mediated ≤ℚ-+ℚ-mono^l forge full bilateral monotonicity.

Consequence: Rational addition is monotone in both arguments; every later ε-shift carries through cleanly without re-proving directionality.

Chapter 36

K_{12} Iteration and Word Algebra

Every iterated application of the K_{12} Laplacian or global-sum operator collapses to a scaled first application. Combined with the annihilation laws $JL = LJ = 0$, this forces every word in the free monoid on $\{L_{12}, J_{12}\}$ to reduce to one of exactly four normal forms: identity, pure L-power, pure J-power, or zero. These relations force all iterated behaviour from the quadratic identities of the Triple K_4 and K_{12} spectral chapter. Induction then eliminates every mixed word except the four surviving normal forms and fixes the complete word algebra.

$\mathbf{Vec}_{12}$ Transport

Reflexivity, symmetry, transitivity for pointwise equality, plus congruence of the sum, scaling, and Laplacian operators. All transport ambiguity is eliminated by fixing how Vec_{12} equalities pass through the three basic operators used in the iteration laws.

Constraint: Without an equivalence relation on $\mathrm{Vec}_{12}\mathbb{Z}$ that is congruent under Σ_{12}, scaling, and the Laplacian, every iteration law would have to be re-proved with bespoke transport at each step and the operator-collapse identities would not chain.

Construction: The triple Vec12Eq-refl/-sym/-trans forges the equivalence; the three congruence lemmas (sum, scaling, Laplacian) lift pointwise equality through every operator used downstream.

Consequence: Vec12Eq is a setoid congruent under all three operators. Every later iteration law transports through it without restatement.

```

Iterated Operator Collapse

Laws 14K.0–14K.2: every iterate of L_{12} or J_{12} beyond the first is a 12-scaled copy of its predecessor. The quadratic identities from the previous chapter force every longer pure iterate to collapse immediately to a scaled first action.

Constraint: If pure iterates of L_{12} or J_{12} did not collapse to scalar multiples of the first action, the operator algebra would have an infinite-dimensional growth and the word-classification of the next section could not terminate in four cases.

Construction: Law 14K.0 forges the two-step recurrence $L_{12}^{n+2} = 12 \cdot L_{12}^{n+1}$ from the quadratic identity law14H-11-LL-twelveL. Laws 14K.1–14K.2 chain it via Vec12Eq-trans into the closed form $L_{12}^{n+1} = 12^n \cdot L_{12}$ (and dually for J_{12}).

Consequence: The operator monoid generated by $\{L_{12}, J_{12}\}$ on pure words collapses to scalar-times-first-letter. Word classification is reduced to a finite case analysis on whether L and J both occur.

```

Word Classification

The free monoid on two generators $\{L, J\}$ evaluates to operators on $\mathrm{Vec}_{12}\mathbb{Z}$. Every word is classified into one of four cases: empty (identity), pure L-power, pure J-power, or mixed (zero). Law 14L.0 forges a total, computational classifier that assigns every word a canonical case together with an operator equality. The classifier is deterministic by construction; uniqueness up to operator equality is not asserted and would require injectivity of caseOp on distinct cases, which is not proved here.

Constraint: If a fifth word class survived (e.g. a non-trivial mixed word that did not collapse to zero), the operator algebra of L_{12} and J_{12} would carry hidden generators and the spectral package of the next chapters would lose its closed form.

Construction: Law 14L.0 recurses on the word: empty $\to$ identity; appending a generator runs $\mathrm{stepCase}$, which dispatches across eight cases (Lg/Jg $\times$ empty/Lpow/Jpow/mixed) and discharges each by Laws 14K.1–14K.2 or by the operator-annihilation identities $L_{12} \circ J_{12} = 0$ and $J_{12} \circ L_{12} = 0$. The resulting class is determined by the generator sequence.

Consequence: Every word factors through one of four canonical cases together with a witnessed operator equality. The classifier is total and deterministic; injectivity of caseOp on distinct cases is not asserted at this stage.

Chapter 37

Rational Multiplication and ε-Splitting

Rational multiplication must be associative, unital, and distribute over addition; these properties are forced by the underlying integer arithmetic. The second half of the chapter derives the ε-splitting lemma: for any positive ε, a quarter-denominator rational δ satisfies $\delta + \delta < \varepsilon$, the key ingredient for combining two Cauchy bounds. Cross-multiplication coherence must survive triple products and distributive expansion, and these same constraints force the small-denominator witness used in the splitting laws.

Rational Multiplication Laws

The multiplication algebra on $\mathbb{Q}$ is forced by reducing every claim to integer associativity, commutativity, and distributivity. No extra multiplicative freedom survives the cross-product setoid.

Constraint: If $\mathbb{Q}$-multiplication acquired any law not derivable from $\mathbb{Z}$-multiplication and $\mathbb{N}^+$-multiplication of denominators, the cross-product setoid would carry hidden algebraic structure and downstream metric estimates would split into incompatible normal forms.

Construction: The triple-product helpers ${}^+\mathrm{to}\mathbb{Z}\text{-}{*^+}\text{-}\mathrm{assoc}^r/\text{-}\mathrm{assoc}^l$ forge the canonical associator on $\mathbb{N}^+$ via the homomorphism $\mathbb{N}^+ \to \mathbb{Z}$ and integer associativity. Every later rational law chains refl-equational steps through these helpers.

Consequence: $\mathbb{Q}$-multiplication is a commutative ring operation forced entirely by the underlying integer ring; no extra rational-level structure is introduced.

Reciprocal on the positive sector

The next forced arithmetic step is an inversion law. The only layer where reciprocals exist without case-splitting on sign is the strictly positive sector of ℚ: positivity can be reflected to the numerator, the numerator can be exposed in successor form, and then denominator and numerator-magnitude can be swapped to produce a reciprocal whose product with the original rational collapses back to 1.

ε-Splitting Laws

For any positive $\varepsilon = a/b$, define $\delta = 1/(4b)$. Then $0 < \delta$ and $\delta + \delta < \varepsilon$. This makes it possible to combine two Cauchy-style bounds into one. The section forces a canonical small witness from the denominator of ε, with no threshold parameter left to choose.

Constraint: A Cauchy-style estimate that allowed a free choice of δ would carry an external parameter into every later metric law. The bound $\delta + \delta < \varepsilon$ must be witnessed by a canonical denominator-derived δ or no triangle estimate would close.

Construction: ϵQuarter reads $\delta = 1/(4b)$ directly off $\varepsilon = a/b$. The positivity witness $0 < \delta$ and the doubling bound $\delta + \delta < \varepsilon$ are forged by integer arithmetic on the denominators halfDen and quarterDen.

Consequence: Every ε-bound carries a canonical δ-companion. No threshold parameter survives; the Cauchy combinator is parameter-free.

Chapter 38

Rational Distance Laws

Every metric space axiom for $d_{\mathbb{Q}}$ is forced by the cross-multiplication setoid on $\mathbb{Q}$. Self-distance is zero (reflexivity), $|x - y| = |y - x|$ (symmetry), the triangle inequality $d(p, r) \leq d(p, q) + d(q, r)$ is an integer-level scaling argument, and translation/multiplicative invariance follow by factoring out common denominator squares. The absolute-value numerator and the cross-multiplication denominators must remain coherent under addition, negation, and multiplication. These constraints force the full metric algebra of $\mathbb{Q}$, including the key bounded-by-ε laws used later in the Cauchy closure arguments.

Metric Axioms

The core metric axioms for $d_{\mathbb{Q}}$ are forced here. Each axiom collapses to integer absolute-value identities together with denominator coherence in the rational setoid.

Constraint: A rational metric that failed reflexivity, symmetry, or non-negativity would not embed into the Cauchy-completion of $\mathbb{Q}$ and the later limit calculus would lose its foundation.

Construction: $\mathrm{dist}\mathbb{Q}$-refl, $\mathrm{dist}\mathbb{Q}$-sym, and the non-negativity lemma each reduce to identities on $|x \pm x|$ and the cross-product equality of the rational setoid. The integer absolute-value congruence $\mathrm{abs}\mathbb{Z}$-cong carries the reductions through.

Consequence: $d_{\mathbb{Q}}$ satisfies reflexivity, symmetry, and non-negativity by construction. The triangle inequality of the next section completes the metric axioms.

Triangle Inequality

The triangle inequality $d(p,r) \leq d(p,q) + d(q,r)$ is forced by multiplying the base scaled-numerator inequality through by a common positive factor $s = (b \cdot d) \cdot f$, then regrouping the six resulting terms. The estimate is forced by integer associativity and distributivity carried through the cross-product setoid once all three distances are expressed over the same positive scale.

Constraint: Without the triangle inequality, $d_{\mathbb{Q}}$ would not be a metric and no later ε-Cauchy argument would compose. The estimate must be uniform in the three denominators or the cross-product setoid would split.

Construction: The proof clears all three denominators by the common positive scale $s = (b \cdot d) \cdot f$, applies $|x + y| \leq |x| + |y|$ on the integer numerators, then regroups the six resulting terms by integer associativity and distributivity. The cross-product setoid carries the estimate back to the rational form.

Consequence: $d_{\mathbb{Q}}$ is a metric. The Cauchy combinator and the ε-splitting laws of the previous sections compose freely into limit estimates.

Translation Invariance

Adding the same rational to both endpoints cannot change distance: the r-contributed terms cancel exactly, leaving the base difference multiplied by a denominator square f^2. Translation dependence is eliminated by forcing those added terms to cancel on the nose.

Constraint: If translation by a common term changed $d_{\mathbb{Q}}$, the metric would carry an absolute origin and the later limit-of-difference arguments would split between left- and right-shifted versions.

Elimination: The added r-contributed terms cancel by integer additive inverse on each numerator; the residual factor f^2 on the denominator is killed by the cross-product setoid equivalence. Every translation alternative collapses onto the base distance.

Consequence: $d_{\mathbb{Q}}$ is translation invariant. The metric is intrinsic to the difference, with no origin dependence.

Multiplicative Scaling

Multiplying both endpoints by the same rational p scales the distance by $d(p, 0)$. This follows from factoring $Z = ab \cdot \text{baseQR}$, then pulling $|ab|$ apart via the multiplicativity of $|\cdot|$. The scaling law is therefore forced by a single common factor rather than by any separate metric assumption.

Constraint: If multiplicative scaling carried a separate metric assumption beyond the multiplicativity of $|\cdot|$, the metric would acquire a second algebraic axiom independent from the ring structure and the limit calculus would split into ring- and metric-incompatible normal forms.

Construction: The proof factors the cross-product numerator Z as $ab \cdot \text{baseQR}$, then pulls $|ab|$ apart via the integer absolute-value multiplicativity $\text{abs}\mathbb{Z}\text{-}{*}\mathbb{Z}$. The cross-product setoid recombines into the product distance.

Consequence: $d_{\mathbb{Q}}(p \cdot q, p \cdot r) = d_{\mathbb{Q}}(q, r) \cdot d_{\mathbb{Q}}(p, 0)$. The metric and the ring share one multiplicativity axiom; no second one is admitted.

Distance Bounds

The key bounding lemma: if $x \leq y + \varepsilon$ and $y \leq x + \varepsilon$ then $d(x, y) \leq \varepsilon$. The proof factors the cross-multiplication into $|d \cdot f| \leq e \cdot bd$ using the absolute-value within-bound lemma. The converse extractions recover one-sided order bounds from a distance certificate, closing the gap between order certificates and metric certificates.

Constraint: Without the order/metric bridge, ε-Cauchy bounds could not be converted into rational-order bounds and the later limit-of-monotone-sequence arguments would lose their bridge into the metric calculus.

Construction: $\mathrm{dist}\mathbb{Q}$-bounded-by-ϵ factors the cross-multiplication via the absolute-value within-bound lemma $|x| \leq y \Leftrightarrow -y \leq x \wedge x \leq y$ on the scaled numerators $d \cdot f$ and $e \cdot bd$. The converse extractions invert the same bridge to recover one-sided order bounds.

Consequence: Order bounds and metric bounds are inter-convertible. The metric calculus and the rational order share one bound interface.

The rational distance function is fully operational: triangle inequality, translation invariance, multiplicative scaling, ε-splitting, and distance-order interconversion are all established. Together with the additive and multiplicative order laws from the preceding chapters, $\mathbb{Q}$ is a complete ordered field except for one property: metric completeness. Not every Cauchy sequence of rationals converges to a rational. That deficiency, once named, forces the next construction.

The Archimedean property of $\mathbb{Q}$ must be made explicit so that convergence estimates can quantify "how fast" sequences approach their limits. With Archimedean scaling in hand and the operator span of K_{12} reduced to its canonical (I, J)-basis, the spectral action of the Laplacian completes the rational infrastructure. After that, no further rational law is needed—only the passage to the reals remains.

Chapter 39

Archimedean Scaling

The Archimedean property for $\mathbb{Q}$: given any $\varepsilon > 0$ and any natural number m, there exists $\delta > 0$ such that $\delta \cdot (m+1) < \varepsilon$. This is forced by the existence of denominators that grow faster than linear factors, together with the half-epsilon infrastructure. The required denominator must be forced from the scaling count and the denominator of ε, leaving no arbitrary choice in the witness construction. The resulting witness collapses to the forced half-epsilon bound and supplies the scaling control needed in the Cauchy convergence arguments.

Chapter 40

$\mathbb{Z}$-Span of K_{12} Operators

The identity operator I and the all-ones operator J (which maps every vector to the constant vector of its sum) span a forced sub-algebra of $\mathrm{End}(\mathrm{Vec}_{12}\mathbb{Z})$. Every operator of the form $a{\cdot}I{+}b{\cdot}J$ is uniquely determined by its coefficients (a, b), and composition closes inside the span with the multiplication rule $(a, b){\cdot}(c, d) = (ac,\ ad{+}bc{+}12bd)$. The coefficients are forced by evaluating a single delta vector, which eliminates every alternative representation and fixes composition inside the same span.

Span Infrastructure

The (I, J)-span on Vec_{12} becomes usable only after the identity action, blockwise scaling, and the linear form $aI + bJ$ are pinned down without representational slack.

Constraint: Every later coefficient-extraction proof reads off the action of $aI + bJ$ on a chosen delta vector. Without a fixed identity operator, blockwise scalar multiplication, and a canonical (a, b)-form, those proofs would split across alternative formulations and the singleton coefficient claim would not hold.

Construction: I12 is forged as the identity on Vec12$\mathbb{Z}$; scaleVec4$\mathbb{Z}$ and scaleVec12$\mathbb{Z}$ as pointwise/blockwise scalar multiplication; linIJ a b v as $a{\cdot}v{+}b{\cdot}J\,v$. The three block-projection lemmas close by refl.

Consequence: The span carrier is fixed without representational slack. Every downstream argument reads $aI + bJ$ in exactly one form, and block-wise reasoning is licensed by the three definitional projection lemmas.

```
-- § identity operator on Vec12ℤ
I12 : Op
I12 v = v

-- § scale a 4-vector by integer a
scaleVec4ℤ : ℤ → Vec4ℤ → Vec4ℤ
scaleVec4ℤ a v i = a *ℤ v i

-- § scale a 12-vector blockwise
scaleVec12ℤ : ℤ → Vec12ℤ → Vec12ℤ
scaleVec12ℤ a v = scaleVec4ℤ a (block₀ v) , (scaleVec4ℤ a (block₁ v) , scaleVec4ℤ a (block₂ v))
```

```
-- § linear combination a·I + b·J
linIJ : ℤ → ℤ → Op
linIJ a b v = scaleVec12ℤ a v +Vec12ℤ scaleVec12ℤ b (J12Vec12ℤ v)

-- § block projection lemmas (all refl)
block₀-linIJ : (a b : ℤ) → (v : Vec12ℤ) → (i : Fin4) →
 block₀ (linIJ a b v) i ≡ (a *ℤ block₀ v i) +ℤ (b *ℤ sum12ℤ v)

 block₁ (linIJ a b v) i ≡ (a *ℤ block₁ v i) +ℤ (b *ℤ sum12ℤ v)
block₁-linIJ a b v i = refl

block₂-linIJ : (a b : ℤ) → (v : Vec12ℤ) → (i : Fin4) →
 block₂ (linIJ a b v) i ≡ (a *ℤ block₂ v i) +ℤ (b *ℤ sum12ℤ v)
block₂-linIJ a b v i = refl
```

Sum-Scaling Laws

Every later coefficient extraction depends on the sum-behaviour of the span operations collapsing through addition and scalar multiplication in exactly one way.

Constraint: If the $\sum$-operator did not commute with addition and scaling in a single canonical way, downstream coefficient extractions would branch on the order of summation and the canonical (a, b)-form would lose uniqueness.

Construction: The six-term reassociation shuffle3Pairs together with the sum-of-add and sum-of-scale lemmas are forged by equational chaining over ℤ, with each step justified by commutativity, associativity, and distributivity already proved in the integer infrastructure.

Consequence: Sum, addition, and scalar multiplication on Vec12ℤ commute in exactly one canonical pattern. Every later proof that extracts a coefficient from a sum expression has a unique normal form to target.

Twelve-Times Commutativity

Multiplication must commute with the forced twelve-times operator—otherwise the composition formula for the (I, J)-span inherits ambiguity from the scalar side.

Constraint: If $x \cdot (\mathrm{fourTimes}\, y)$ did not collapse to $\mathrm{fourTimes}\,(x \cdot y)$, the composition rule for (I, J)-span elements would carry a free reordering and the canonical (a, b)-form would lose uniqueness on composites.

Construction: Each commutativity lemma is forged by distributing multiplication across the explicit four-term sum and reassembling the result via the integer-ring identities. The proofs are equational chains in $\mathbb{Z}$ closed by trans and cong.

Consequence: Multiplication and the twelve-times operator commute in a single canonical pattern. The composition formula for (I, J)-span elements inherits this rigidity unchanged.

Delta Vectors

Coefficient extraction requires delta witnesses whose support and total sum leave no room for choice: once the delta vector is fixed, every coefficient is read off rather than selected.

Constraint: Without a fixed delta basis the extraction $\mathrm{linIJ}\ a\ b\ (\delta_g\ x) \to (a, b)$ would split across alternative supports and the singleton (a, b) would no longer be forced.

Construction: The delta vector $\delta_g\ x$ is forged by exhaustive pattern-matching over the four positions of Fin_4, and lifted to $\mathrm{Vec12}\mathbb{Z}$ blockwise. The total-sum identity $\mathrm{sum12\text{-}delta12}$ closes by refl on each constructor.

Consequence: The delta vectors form a fixed extraction basis. Coefficient evaluation on $\delta_g\ x$ is a definitional read-off, leaving no room for representational drift.

Forced Independence and Uniqueness

Coefficient multiplicity in the (I, J)-span collapses completely: evaluation on the canonical delta vector forces independence first, then forces uniqueness of every coefficient pair.

Constraint: If two distinct pairs $(a, b) \neq (a', b')$ produced the same operator linIJ, the span would not be a normal form and the spectral package would carry hidden ambiguity at every coefficient extraction.

Elimination: Evaluation on the delta vector δ_{g_1} 1 separates the **I**- and **J**-contributions: at position g_1 the **I**-term vanishes and the equation extracts b; at position g_0 the **I**-term recovers a. Any second pair satisfying the same operator equation collides with these extractions.

Consequence: Independence of **I** and **J** is forced, and the coefficient pair (a, b) is the unique span witness of every operator in the image.

Packaging and Composition Closure

Packaging the span coefficients and closing them under composition is forced by the sum and scaling identities already established—no alternative closure rule survives.

Constraint: Without composition closure, the product of two span elements could escape the (I, J)-form and downstream algebraic chains would break at the first composite. The package interface must collect the coefficient pair, the operator equality, and the closure law into a single witness.

Construction: SpanIJ is forged as $\mathbb{Z} \times \mathbb{Z}$ with interpIJ as the canonical interpretation, and mulSpanIJ as the closed multiplication law. The composition closure law law14N-3-IJ-compose-closed is discharged by sum and scaling identities already proved.

Consequence: The span is a closed subalgebra of the operator ring. Every composite of span elements has a unique normal-form witness in $\mathbb{Z} \times \mathbb{Z}$.

```

Chapter 41

Forced Spectral Action of the (I, J)-Span

The $(\mathbf{I}, \mathbf{J})$-span established in Ch. 40 provides normal-form coefficients for every endomorphism of $\mathrm{Vec}_{12}\mathbb{Z}$ belonging to that span. This chapter forces the *spectral decomposition*: every $(a \cdot \mathbf{I} + b \cdot \mathbf{J})$ is forced to act as scalar multiplication by a on sum-zero vectors and by $a + 12b$ on constant vectors, and these two predicates are forced invariant under every span element. The K_{12} Laplacian is then identified as the concrete span element $(12, -1)$, and the full eigenvalue-exhaustion theorem is established: no eigenvalue other than $\lambda = 12$ or $\lambda = 0$ is possible for a nonzero vector. The normal-form coefficients therefore force the spectral action, the Laplacian identification, and finally the exhaustive eigenvalue elimination.

Forced Predicates on $\mathrm{Vec}_{12}\mathbb{Z}$

The two predicates—sum-zero and constant—that will serve as invariant subspaces for the (I, J)-span are defined as Σ-witnesses, ensuring downstream consumers receive constructive content. Only two subspaces survive the later spectral elimination.

Constraint: A propositional formulation of "sum-zero" or "constant" would conceal the data needed for downstream transport. The two invariant subspaces must carry constructive content, otherwise the spectral package cannot extract the eigenvalue-defining scalar.

Construction: $\mathrm{ZeroSumVec12}$ is forged as the equality $\Sigma_{12}\, v \equiv 0$. $\mathrm{ConstVec12}$ is forged as a Σ-pair carrying the witness scalar c together with a pointwise equality to the constant vector. Both predicates are inhabited if and only if the corresponding subspace is.

Consequence: The two predicates are the unique constructive witnesses for the two invariant subspaces. Every later spectral law reads its scalar directly out of the predicate witness.

```
– § Sum-zero and constant predicate witnesses on Vec12ℤ
ZeroSumVec12 : Vec12ℤ → Set
ZeroSumVec12 v = sum12ℤ v ≡ 0ℤ

ConstVec12 : Vec12ℤ → Set
ConstVec12 v = Σ ℤ (λ c → Vec12Eq v (constVec12ℤ c))
```

Congruence of linIJ and interpIJ

Pointwise equality is forced as a precondition for transporting results across different witnesses of the same vector. Without congruence, every later transport would silently introduce representation drift; the spectral chain would unravel at the first substitution. Congruence is therefore not stylistic hygiene but the gate that keeps the representation rigid.

Constraint: Equal-but-not-identical witnesses of the same Vec_{12} vector must produce equal images under linIJ; otherwise spectral transport would lose its identity-of-witness invariant and downstream substitutions would split.

Construction: linIJ-cong is forged blockwise: the sum equality is lifted by sum12-cong and the scalar equalities by cong. interpIJ-cong is the immediate corollary on coefficient pairs.

Consequence: The span representation is a function of the underlying vector, not of its presentation. Every later transport step is licensed by these two congruences without further side conditions.

```

Forced J-Action

The averaging operator **J** acts definitionally as the sum Σ_{12} broadcast to every coordinate. On sum-zero vectors it annihilates; on constant vectors it multiplies by 12. These two actions are the fixed witnesses from which the later span spectrum is forced.

Constraint: Without a fixed **J**-action on the two invariant subspaces, the eigenvalues of $a\,\mathbf{I}+b\,\mathbf{J}$ would not separate into the two spectral classes; the entire two-eigenvalue classification rests on these two laws.

Construction: law14O-0-J-sum0 is forged from the sum-zero hypothesis by reading $\mathbf{J}\,v$ blockwise as the broadcast of $\Sigma_{12}\,v \equiv 0$. law14O-1-J-const is forged from the closed-form $\Sigma_{12}(\mathrm{constVec12}\,c) = 12c$. Both are pointwise constructions that close blockwise.

Consequence: On the sum-zero subspace, **J** vanishes; on the constant subspace, **J** acts as multiplication by 12. These are the only two non-trivial actions of **J** on the forced invariant subspaces.

```
-- § Law 14O.0: sum-zero forces J-annihilation
law14O-0-J-sum0 : (v : Vec12ℤ) → ZeroSumVec12 v → Vec12Eq (J12Vec12ℤ v) zeroVec12ℤ
law14O-0-J-sum0 v sum0 =
 (λ _ → sum0) , ((λ _ → sum0) , (λ _ → sum0))

-- § Law 14O.1: constant vectors force J-scaling by 12
law14O-1-J-const : (c : ℤ) → Vec12Eq (J12Vec12ℤ (constVec12ℤ c)) (constVec12ℤ (twelveTimesℤ c))
law14O-1-J-const c =
 (λ _ → sum12-const c) , ((λ _ → sum12-const c) , (λ _ → sum12-const c))
```

Forced Two-Eigenvalue Classification

Every element $a \cdot \mathbf{I} + b \cdot \mathbf{J}$ of the span is forced to act with eigenvalue a on sum-zero vectors (because the **J**-term collapses) and eigenvalue $a + 12b$ on constant vectors (because the sum of a constant vector is $12c$). Both spectral actions are forced; their joint exhaustiveness is established below in the eigenvalue exhaustion section.

Constraint: The two invariant subspaces—sum-zero vectors and constant vectors—are pinned by the orthogonality of **I** and **J** on each side; the action of $a\mathbf{I} + b\mathbf{J}$ on each subspace must therefore reduce to a single scalar.

Construction: On a sum-zero vector the **J**-term vanishes, so the action collapses to scaling by a. On a constant vector the sum equals $12c$, so the action collapses to scaling by $a + 12b$. Both equations are forged by direct computation in $\mathbb{Z}$ and packaged as Vec12Eq-witnesses.

Consequence: Within the span and on its two invariant subspaces, the eigenvalue is determined by the vector class. The exhaustion theorem closes the spectrum to exactly $\{12, 0, 0\}$ by the torsion-free upgrade.

Forced Predicate Invariance Under the (I, J)-Span

Both the sum-zero and constant predicates are forced to be invariant under every element of the (I, J)-span. The sum-zero invariance follows from the forced closed form of $\Sigma_{12}(\text{linIJ } a\ b\ v)$; the constant invariance follows from sum congruence and the eigenvalue structure of Law 14O.3. This eliminates any gap between algebraic normal form and the spectral predicates.

Constraint: If the two invariant subspaces were not closed under the span action, the spectral package would have to track exit witnesses for every coefficient pair; the singleton spectral interpretation would split.

Construction: law14O-8-linIJ-preserves-sum0 is forged from the closed form $\Sigma_{12}(\text{linIJ } a\, b\, v) = (a + 12b)\, \Sigma_{12}\, v$; substituting $\Sigma_{12}\, v = 0$ yields 0. law14O-9-linIJ-preserves-const is forged by transporting the constant witness through the eigenvalue law on constants.

Consequence: The sum-zero and constant subspaces are span-stable. Any algebraic argument inside the span carries the spectral classification through unchanged.

Spectral Package for linIJ

The four forced spectral facts—sum-zero invariance, constant invariance, sum-zero eigenvalue a, constant eigenvalue $a + 12b$—are bundled into a single witness type so that downstream consumers need only one import. Packaging adds no new freedom; it only collects the already-forced facts into a single interface.

Constraint: Four independent spectral facts about linIJ are already forced. Without a unified package interface, every downstream consumer would have to assemble them in the same order, opening room for inconsistent assembly orders across the book.

Construction: LinIJSpectralPackage is forged as the Σ-product of the four forced spectral facts. The constructor law14O-10-linIJ-spectral-package populates each component from the already-proved laws; four projection helpers expose them.

Consequence: Every downstream consumer receives the spectral data in a single canonical bundle. Coefficient pair and spectral facts collapse into one witness.

```

Transport from Normal Form to Spectral Facts

Any operator f that possesses a span witness $f = a \cdot \mathbf{I} + b \cdot \mathbf{J}$ inherits all four spectral facts by composing the pointwise equality with the corresponding forced law for $\mathrm{linIJ}\ a\ b$. The transport step eliminates any distinction between an abstract span witness and its normal-form representative.

Constraint: An operator known to equal $a \cdot \mathbf{I} + b \cdot \mathbf{J}$ pointwise must inherit every spectral invariant already proved for the normal form $\mathrm{linIJ}\ a\ b$. If the transport fails, the span decomposition carries no spectral content.

Construction: Each of the four spectral facts (sum-zero invariance, constant invariance, sum-zero eigenvalue, constant eigenvalue) is lifted through the pointwise equality witness via $\mathrm{Vec12Eq\text{-}trans}$. The construction is forced: the only bridge from an abstract operator to a concrete normal form is pointwise composition.

Consequence: After transport, any span-witnessed operator carries the full spectral package. The distinction between "has a span witness" and "obeys the spectral laws" collapses.

```
– § Law 14O.11: any f with witness f=(a·I+b·J) inherits the spectral facts

Span Witness Packages

The coefficient pair (a, b) witnessing $f = a{\cdot}\mathbf{I} + b{\cdot}\mathbf{J}$ is forced unique by Law 14N.2. The coefficient pair and spectral facts collapse into one canonical witness so that downstream consumers receive a single import. All remaining witness multiplicity at the package level is thereby eliminated.

Constraint: An operator f that admits a span representation could carry several coefficient pairs (a, b) if uniqueness were not forced; downstream spectral arguments would then branch on the choice of pair.

Construction: SpanIJSpectralPackage is forged as the Σ-package of the coefficient pair and the operator equality. The uniqueness law law14O-12-spanIJ-witness-unique reduces to law14N-2-image-witness-unique, which was already discharged.

Consequence: Every operator in the span carries exactly one coefficient pair, exposed by the package projections. Spectral facts read off this pair are the unique spectral profile of the operator.

```
-- § Law 14O.12: span-IJ coefficient witness is forced unique
SpanIJSpectralPackage : Op → Set
SpanIJSpectralPackage f = Σ SpanIJ (λ p → OpEq f (interpIJ p))

```

Unified Span Transport Package

The unified package collects the coefficient pair, the pointwise equality, and both the operator and the linIJ-level spectral facts into a single record. The package is forced because each component is fixed uniquely by the preceding laws.

Constraint: Three layers of spectral data—operator equality, transported facts, normal-form facts—live separately. Without a unified record, downstream consumers would have to recombine them, leaving room for misaligned witnesses.

Construction: SpanIJUnifiedPackage is forged as the Σ-record of all three layers. The constructor law14O-14-spanIJ-unified-package populates the unified record from a span witness via law14O-11-spanIJ-transport and law14O-10-linIJ-spectral-package. Six projection helpers expose every component; uniqueness of coefficients reduces again to law14N-2-image-witness-unique.

Consequence: The unified package is the canonical interface between an operator and its span representation. Every later consumer receives one record and projects whatever spectral fact it needs.

```
-- § Law 14O.14: unified span transport package
SpanIJUnifiedPackage : Op → Set

Helper Coefficients

The integer $12 \in \mathbb{Z}$ is definitional from twelveTimesℤ oneℤ; its positivity witness reduces to a constructor equation. The following identities fix the coefficient forms needed to identify the Laplacian inside the (I, J)-span.

Constraint: The Laplacian identification requires the integer constants 12 and -1 in canonical form, together with their definitional behaviour under multiplication. Without these helpers, the span witness $(12, -1)$ could not be discharged by refl.

Construction: twelveℤ is forged as twelveTimesℤ oneℤ; twelveℤ-pos as the explicit +suc-witness. twelveℤ-*ℤ-left and negOne-*ℤ-left are forged by integer-ring rewriting to expose the canonical multiplication patterns.

Consequence: The integer constants needed to recognise the Laplacian as a span element are in canonical form. Every later identification of the Laplacian with $(12, -1)$ closes by these helpers without further bookkeeping.

```
-- § Forced integer 12

Laplacian as a Forced (I, J)-Span Element

The K_{12} Laplacian is identified as the concrete span element $(12, -1)$. Pointwise, $L_{12}\, v_i = 12\, v_i - \Sigma_{12}\, v$, which matches linIJ 12 (-1) v once the multiplication lemmas collapse.

Constraint: The Laplacian must occupy a fixed position inside the span calculus, otherwise its spectral facts could not be obtained by transport from the normal-form package. The position must be a single coefficient pair, not a parametrised family.

Construction: The pointwise identity $L_{12}\, v = 12 \cdot v - \Sigma_{12}\, v = \mathrm{linIJ}\, 12\, (-1)\, v$ is forged blockwise. Each block reduces by twelveℤ-*ℤ-left and negOne-*ℤ-left to the canonical linIJ-form.

Consequence: The Laplacian is the span element $(12, -1)$. Every spectral fact for linIJ 12 (-1) transports to L_{12} via law14O-11-spanIJ-transport without further proof.

```
-- § Law 14O.4: L₁₂ is forced to equal (12·I)+(−1)·J

```

Laplacian Composition Closure

The Laplacian, identified as the span element $(12, -1)$, is closed under composition with every other span element via the composition law 14N.3. Composition closure eliminates any residual doubt that the concrete Laplacian lies outside the forced span calculus.

Constraint: Without composition closure for the Laplacian, polynomial identities involving L_{12} could exit the span and lose their unified spectral interpretation.

Construction: Left and right composition with L_{12} are forged via law14N-3-IJ-compose-closed applied to the witness $(12, -1)$. Each closure law extends to the unified package by composition with law14O-14-spanIJ-unified-package.

Consequence: Every polynomial in L_{12} over $\mathbb{Z}$ stays inside the span. The forced spectral package extends to all such composites without additional witnesses.

Forced Laplacian Eigenvalues

The two Laplacian eigenvalues are direct consequences of the span identification $(12, -1)$: sum-zero forces eigenvalue 12, constants force eigenvalue 0. These are the only two spectral actions that survive on the forced invariant subspaces.

Constraint: Without an explicit eigenvalue computation, the two-class spectral picture would remain abstract; downstream users would have to recompute the action of L_{12} on each subspace.

Construction: Sum-zero eigenvalue 12 is forged by transporting law14O-2-linIJ-sum0-eigen through the span identification of L_{12}. Constant eigenvalue 0 is the immediate corollary $L_{12}(\mathrm{constVec12}\, c) = \mathrm{zeroVec12}$ already proved as law14H-14-const-eigen0.

Consequence: The Laplacian acts as multiplication by 12 on sum-zero vectors and annihilates constants. No third eigenvalue can appear without violating one of these two laws.

```

```

Laplacian Spectral Package

The complete Laplacian spectral package bundles all forced spectral behaviour into a single witness: span membership, drift (sum of image is zero), JL-annihilation, sum-zero eigenvector characterisation, image containment, and constant kernel. The package adds no new structure; it only collects the already-forced Laplacian facts.

Constraint: Seven independent forced facts about L_{12} exist: span membership, drift, $\mathbf{J}L$-annihilation, the two eigenvalue laws, image containment, and the constant kernel. Without a single record, downstream consumers would assemble them by hand.

Construction: L12SpectralPackage is forged as the seven-component Σ-record. Each component reduces to an already-proved law. The constant-kernel projection is named separately for use as a Σ-witness elsewhere.

Consequence: The full forced spectral profile of L_{12} is one record. Every later spectral consumer reads exactly the data it needs from this package, with no re-derivation.

Eigen-Constraint Refinements

The "reverse direction" facts from the Triple K_4 and K_{12} spectral chapter are re-stated in the scaleVec12ℤ language of the (I, J)-span. This section removes the remaining mismatch between old operator notation and the forced span normal form.

Constraint: The earlier eigenvalue laws speak in operator notation; the span calculus speaks in scaleVec12ℤ. Without a translation layer, the eigenvalue-to-subspace direction would not transport into the unified package and downstream consumers would face two incompatible eigenvalue interfaces.

Construction: law14O-21-scale12≡twelveVec12 and law14O-22-scale0≡zeroVec12 forge the bridge between scaling and the named vectors. The reverse-direction laws law14O-23 and law14O-24 are then forged by composing the bridges with the already-proved triple-Laplacian implications.

Consequence: Every eigenvalue statement in either notation transports cleanly to the other. The unified spectral package speaks one language; downstream consumers face no translation overhead.

Torsion-Free Kernel Upgrade

The kernel constraint $12 \cdot v = \mathbf{J}\, v$ forces all coordinates to share the same 12-multiple. Once the positivity witness $12 = +\mathrm{suc}\ 11$ is supplied, torsion-freeness eliminates all remaining coordinate freedom and forces v itself to be constant. This is the step that collapses the kernel witness from scaled constancy to actual constancy.

Constraint: The naive kernel witness yields $12 \cdot v_i = \Sigma_{12}\, v$ for every coordinate—a scaled-constancy condition. Without torsion-freeness over $\mathbb{Z}$, the unscaled coordinates could still differ and the eigenvalue-0 subspace would be wider than the constants.

Elimination: Torsion-freeness on $\mathbb{Z}$ via $^*\mathbb{Z}$-pos-left-zero→zero kills every alternative coordinate value: from $12 \cdot (v_i - v_0) = 0$ and $12 = +\mathrm{suc}\ 11$ it forces $v_i = v_0$ at every position. The positivity witness twelve$\mathbb{Z}$-pos discharges the side condition; the cancellation proof cancel12 carries the elimination through every block.

Consequence: Eigenvectors for eigenvalue 0 are exactly the constant vectors. The eigenvalue-0 subspace is the constant subspace—no wider, no narrower.

Eigenvalue Exhaustion

The earlier laws force the constraints for $\lambda = 12$ and $\lambda = 0$. Every eigen-equation is forced to fall under $\lambda = 12$, $\lambda = 0$, or the zero vector. The key ingredient is the Laplacian's commutativity with scaling and torsion-freeness over $\mathbb{Z}$. Every further eigenvalue candidate is eliminated as incoherent.

Constraint: A third eigenvalue candidate $\lambda \notin \{12, 0\}$ would split the spectral classification and reopen the singleton claim about the (I, J)-span. The exhaustion proof must close every alternative.

Elimination: Commutativity of the Laplacian with scaling combined with torsion-freeness over $\mathbb{Z}$ kills every $\lambda \notin \{12, 0\}$ on a non-zero vector: the equation $L_{12}\, v = \lambda\, v$ forces λ into one of the two known eigenvalues, or forces v to be the zero vector.

Consequence: The Laplacian spectrum on $\mathbb{Z}^{12}$ is exactly $\{12, 0\}$. No third eigenvalue is admissible. The K_{12} Laplacian carries an $\mathrm{Aut}(K_4)$-invariant numeric trace via its K_4 block-construction; the eigenvalues 12 and 0 are forced by combinatorial structure of the underlying graph rather than by external choice.

Corrected Ausschlussgesetz

The eigenvalue exhaustion (Law 14O.35) combines with the forced constraint laws (Law 14O.32) to produce the unique coherent eigenvector classification: $\lambda = 12$ forces sum-zero, $\lambda = 0$ forces constant, and every other λ forces the zero vector. The final exclusion law is packaged with no surviving branch left open.

The rational measurement layer expresses the spectral content exactly. Quotients, distances, finite-index operators, coupled and triple K_4 Laplacians, word algebra, and rational order describe the combinatorial data without leaving gaps at the level of explicit calculation. The graph evaluation $\mathcal{C} = 137$ is computed as a Simplex-Euler invariant in Chapter 28; the spectral eigenvalues $\{0, 4\}$ of K_4 are determined; and the 3:1 eigenspace split is a forced structural consequence of the four-vertex completion. These numbers emerge from the graph. What the remaining chapters establish is that they cannot emerge from any other source.

What remains is not another finite algebraic law but closure itself. Once the metric structure is explicit, Cauchy data that does not settle inside $\mathbb{Q}$ must be given a legitimate home. The next step is therefore forced completion: the passage from rational measurement to the reals.

Figure 41.1 fixes that transition in one glance. Rational points do not disappear; they embed as constant sequences. What changes is that the metric space is no longer allowed to leak Cauchy processes that have nowhere to land. The closure adds precisely those limit points the rational layer could approach but not contain.

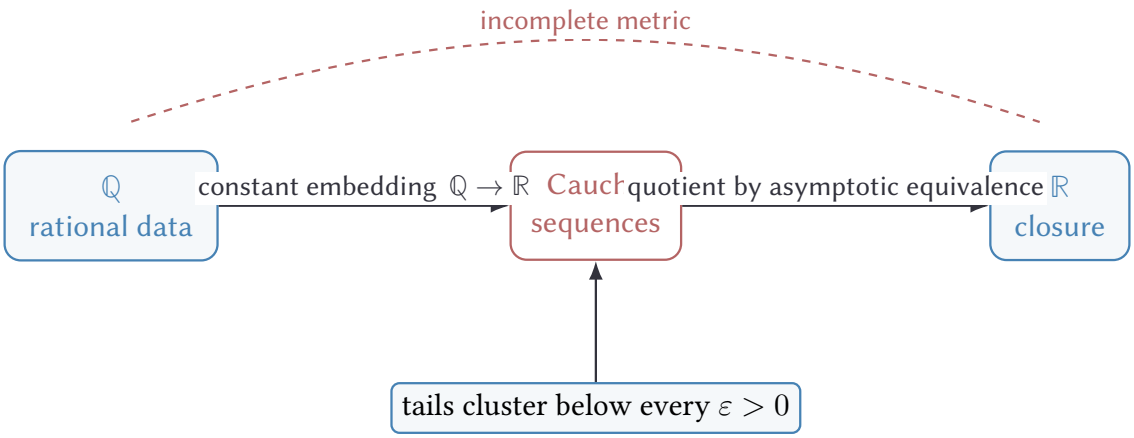

Figure 41.1: Forced Cauchy closure: $\mathbb{Q}$ embeds as constant sequences, while the missing limits of rational Cauchy data are closed inside $\mathbb{R}$.

Chapter 42

Reals as Forced Cauchy Closure over $\mathbb{Q}$

The metric on $\mathbb{Q}$ is incomplete, so Cauchy data cannot remain inside $\mathbb{Q}$ without loss. The reals are therefore forced as the Cauchy closure, with arithmetic and order lifted pointwise through explicit preservation proofs. Every later real operation and law is fixed by that single closure step, with no additional parameters.

Cauchy condition and the real number type

A sequence is Cauchy when, for every rational tolerance $\varepsilon > 0$, all sufficiently late terms cluster within ε of each other. A real number is a sequence carrying a proof of this condition. The embedding $\mathbb{Q} \hookrightarrow \mathbb{R}$ sends each rational to the constant sequence, whose Cauchy proof is immediate from $\mathrm{dist}\mathbb{Q}\text{-const}{<}\epsilon$. What follows fixes the only admissible entry point from rational metric data to real closure.

Constraint: The rational metric is incomplete: Cauchy sequences exist whose limits lie outside $\mathbb{Q}$. Without closure, the spectral data computed over the integers has no continuous home.

Construction: A real number is defined as a rational sequence bundled with its Cauchy proof. The embedding $\mathbb{Q} \hookrightarrow \mathbb{R}$ sends each rational to the constant sequence; the Cauchy witness is immediate. No alternative definition survives: any weaker type (bare sequences, sequences without clustering proof) admits non-convergent data.

Consequence: The real number type is the unique forced closure of the rational metric. Every later real operation inherits its structure from this single step.

Real equivalence and symmetry

Without an equivalence relation, Cauchy sequences are merely sequences: distinct as data, indistinguishable as limits. The passage from sequences to real numbers demands a quotient, and the quotient demands a relation that is reflexive, symmetric, and transitive. Once the rational metric is in place, the only relation that captures "same limit" is asymptotic distance elimination: two sequences are equivalent when their pointwise distance is eventually below every positive ε.

The quotient relation on Cauchy data is forced here: two representatives may describe the same real only when their rational distance is eventually eliminated at every positive scale. Symmetry then removes the residual orientation freedom, since the witnessing distance is already fixed by the symmetry law for $\mathrm{dist}\mathbb{Q}$.

Constraint: Equivalent sequences must have vanishing pointwise distance at every positive scale, or the quotient would identify sequences with distinct limits.

Construction: Any identification weaker than pointwise ε-convergence fails to separate distinct limits; any identification stronger collapses sequences that converge to the same value. The only surviving relation is $x \simeq_{\mathbb{R}} y$ iff for every $\varepsilon > 0$ there exists N such that $\mathrm{dist}\mathbb{Q}(x_n, y_n) < \varepsilon$ for all $n \geq N$. Symmetry follows from $\mathrm{dist}\mathbb{Q}$-sym.

Consequence: The equivalence relation is locked. Reflexivity and transitivity are inherited from the metric; symmetry is proved below. No weaker or stronger identification survives.

Addition on ℝ

The Cauchy closure carries sequences, but sequences without operations are inert. If addition is not extended from ℚ to ℝ, the real field never forms, and the later spectral constants have no additive home. The extension is forced to be pointwise: any other rule would sever the sum from the underlying rational terms and destroy the Cauchy property that defines the closure.

Addition on ℝ is forced to be the pointwise lift of rational addition: any other operation would detach the real structure from the Cauchy witnesses that generate it. The proof eliminates instability by quartering ε, pulling Cauchy moduli from both summands, and collapsing the total distance through distℚ-triangle together with the two translation laws for distℚ.

Constraint: Two Cauchy error budgets must be merged without overflow.

Construction: Quarter ε to eliminate cross-term overflow, extract moduli independently from each summand, and drive the total distance below ε via the triangle inequality. Any coarser budget allocation fails the Cauchy condition.

Consequence: Real addition is the unique Cauchy-compatible pointwise lift. No alternative survives.

Negation, subtraction, and constants

Once addition has entered the closure, negation is forced by the demand for additive inverses: without negation, the reals would be a monoid rather than a group, and the later additive algebra laws would have no cancellation target. The key enabler is that the rational metric is already sign-invariant (distℚ-neg), so negating every term of a Cauchy sequence preserves the Cauchy property without any additional ε-budget.

Negation must preserve real structure because the rational metric is invariant under sign reversal through distℚ-neg. Subtraction therefore has no separate freedom beyond addition with negation, and the distinguished constants $0_{\mathbb{R}}$ and $1_{\mathbb{R}}$ are forced as the direct images of the corresponding rational constants.

Constraint: Subtraction must decompose as addition-with-negation so that no independent Cauchy proof is needed.

Construction: Pointwise rational negation is the only operation whose Cauchy proof inherits from distℚ-neg without additional witness data. Any alternative negation either breaks the Cauchy property or fails to invert addition. Subtraction reduces to $x + (-y)$; the constants 0 and 1 embed as constant sequences.

Consequence: The additive group structure is complete. No further algebraic primitive is needed until multiplication.

Additive algebra laws

With addition, negation, and the distinguished constants in place, the additive algebra must now be shown to obey the same laws as $\mathbb{Q}$—commutativity, associativity, identity, and inverse. If any of these failed, the real field would diverge from the rational one it was built to complete, and the later spectral identities could not be transported from $\mathbb{Q}$ to $\mathbb{R}$.

The additive algebra on $\mathbb{R}$ cannot differ from the rational algebra already fixed pointwise on representatives. Each law is forced by the same elimination pattern: take threshold $N = 0$, invoke the corresponding rational identity, and collapse the resulting distance to zero via distℚ-≃0.

Constraint: Every additive law must hold up to $\simeq_{\mathbb{R}}$, not merely pointwise, so that the laws descend to the quotient.

Construction: For each law, the Cauchy threshold collapses to $N = 0$: the corresponding rational identity eliminates all distance between the two sides at every index. No finite-prefix correction survives.

Consequence: Commutativity, associativity, identity, and inverse are forced. The additive group is an abelian group over $\mathbb{R}$.

Eventual boundedness and multiplication

Cauchy closure, once created, cannot remain a purely additive object. If multiplication is left outside the closure, the real field collapses to a module over $\mathbb{Q}$ and loses the self-interaction that every later derived quantity depends on. But admitting multiplication forces a new constraint: the product of two convergent sequences need not converge unless both factors are eventually bounded. Boundedness is therefore not an optional refinement; it is the gate through which multiplication enters, and without it the Cauchy property of the product cannot even be stated.

Multiplication cannot be admitted until eventual boundedness is extracted from every Cauchy representative, because product control requires fixed bounds on one factor while the other factor oscillation is eliminated. The proof first forces a tail bound by evaluating the Cauchy condition at $1_{\mathbb{Q}}$, then decomposes the product distance into two terms and drives each term below $\varepsilon/4$ by the same δ-scaling discipline used throughout the metric development.

Constraint: Without bounded tails, the product distance $|f_n g_n - f_m g_m|$ contains a term proportional to an unbounded factor, so no uniform ε-control exists.

Construction: Extract a tail bound B from the Cauchy condition at tolerance 1, eliminating unbounded growth beyond that tail. Then decompose the product distance via the identity $fg - f'g' = f(g-g') + g'(f-f')$ and drive each summand below $\varepsilon/4$ using the bound and δ-scaling. Any sequence without a finite tail bound is excluded.

Consequence: Multiplication enters $\mathbb{R}$ with its Cauchy property locked to the same ε-quartering discipline that governs addition. No alternative entry survives.

Real multiplication. $\cdot_{\mathbb{R}}$ multiplies Cauchy sequences pointwise. The Cauchy property of the product uses eventual boundedness plus δ-scaling to control the error.

Multiplicative algebra laws

Addition forms a group, but a group alone cannot support the invariant chain: the evaluation constants that will emerge from K_4 are multiplicative invariants, and the spectral identities interleave products with sums. If multiplication on $\mathbb{R}$ does not obey the same algebra as multiplication on $\mathbb{Q}$, the constants lose their ring-theoretic home and the later invariants cannot be defined.

Once multiplication is forced on representatives, its algebraic laws have no remaining freedom: each one is the pointwise lift of the corresponding rational law. The witness pattern is again uniform, with threshold $N = 0$, the rational identity at stage n, and immediate elimination of the induced distance by $\mathrm{dist}\mathbb{Q}\text{-}\simeq 0$.

Constraint: Every multiplicative law must hold up to $\simeq_{\mathbb{R}}$ so that the ring structure descends to the Cauchy quotient.

Construction: For each law, the Cauchy threshold collapses to $N = 0$: the corresponding rational identity eliminates all distance between the two sides at every index, and $\mathrm{dist}\mathbb{Q}\text{-}\simeq 0$ closes the gap. No alternative threshold or identity survives.

Consequence: Commutativity, associativity, identity, and distributivity are forced. Together with the additive group, the reals are a commutative ring—the minimal structure that can host the spectral constants.

Congruence of multiplication and addition

A ring whose operations depend on the choice of representative is no ring at all: congruence is the bridge that turns operations on Cauchy sequences into operations on reals. Without it, the field structure collapses back to raw sequence manipulation, and the spectral constants would vary with the representative chosen—an inadmissible catastrophe.

Congruence removes the last representative dependence: addition and multiplication are admissible on reals only if equivalent Cauchy data are sent to equivalent results. Addition follows the already forced additive control, while multiplication repeats the product decomposition with mixed representatives and uses eventual bounds plus δ-scaling to eliminate both error terms.

Constraint: Both operations must map $\simeq_{\mathbb{R}}$-equivalent inputs to $\simeq_{\mathbb{R}}$-equivalent outputs, or the quotient construction fails.

Construction: For addition, triangle-inequality elimination suffices. For multiplication, decompose the product difference via the identity $xz - x'z' = x(z - z') + (x - x')z'$, then scale each summand by an eventual bound from

texttttIsCauchy-eventually-bounded. Any operation that fails this decomposition is excluded from the quotient.

Consequence: Addition and multiplication are well-defined on the Cauchy quotient. The reals now form a genuine commutative ring, not merely a ring of sequences.

Additive congruence. Addition is simpler: no eventual bounds are needed, only $\varepsilon/4$-convergence in both sequences. The triangle inequality then closes the argument directly.

Asymptotic Order on ℝ

A field without order cannot host inequalities, and inequalities are the language of the invariant chain: every bound, every spectral gap, every convergence statement is an order statement. But reals are equivalence classes of Cauchy sequences, and finite-prefix comparisons do not survive the passage to the quotient. The only order that does survive is asymptotic: a comparison that holds on every tail, for every positive margin.

Order on ℝ is forced to be asymptotic: finite prefixes cannot survive quotient formation, so only eventual rational comparison with arbitrary positive margins remains admissible. The unique strict and non-strict order notions compatible with representative elimination under $\simeq_{\mathbb{R}}$ are fixed below.

Constraint: Order must be compatible with the Cauchy quotient: if $x \simeq_{\mathbb{R}} x'$ and $x \leq_{\mathbb{R}} y$, then $x' \leq_{\mathbb{R}} y$. Any order depending on a finite prefix is shattered by re-choosing the representative.

Construction: Any order definition depending on a finite prefix is shattered by re-choosing the representative. The only surviving definitions are: $x \leq_{\mathbb{R}} y$ iff for every $\varepsilon > 0$ there exists N such that $x_n \leq y_n + \varepsilon$ for all $n \geq N$; and $x <_{\mathbb{R}} y$ iff there exists $\varepsilon > 0$ with the same tail comparison. Every prefix-dependent alternative is eliminated.

Consequence: Twelve order laws are forced—reflexivity, transitivity, antisymmetry, congruence under $\simeq_{\mathbb{R}}$, and additive monotonicity—closing the ordered-field scaffold required by the spectral constants.

Law 23.1: Non-strict asymptotic order

Non-strict order is forced by eventual ε-comparison for every positive rational margin. Any weaker condition leaves room for prefix dependence, and that dependence is already excluded by the quotient from Cauchy representatives to reals.

```
-- § Non-strict real order: eventual ϵ-approximation
infix 4 _≤ℝ_ _<ℝ_

record _≤ℝ_ (x y : ℝ) : Set where
 field
  leReal : (ϵ : ℚ) → (0ℚ <ℚ ϵ) → Σ ℕ (λ N → (n : ℕ) → N ≤ n → (seq x n) ≤ℚ ((seq y n) +ℚ ϵ))

-- § Type alias for non-strict real order
≤ℝP : ℝ → ℝ → Set
≤ℝP = _≤ℝ_
```

Law 23.2: Strict asymptotic order

Strict order is forced by a positive rational witness that survives on a tail. This eliminates vanishing separation and fixes strictness as stable asymptotic margin rather than finite-stage fluctuation.

```
-- § Strict real order: witnessed separation
record _<ℝ_ (x y : ℝ) : Set where
 field
  ltWitness : Σ ℚ (λ ϵ → (0ℚ <ℚ ϵ) × Σ ℕ (λ N → (n : ℕ) → N ≤ n → ((seq x n) +ℚ ϵ) ≤ℚ (seq y n)))
```

Law 23.3: Strict order forces non-strict order

Every strict witness forces non-strict order once the positive gap is forgotten after it has done its work. The margin survives only as an intermediate constraint and is then eliminated from the final asymptotic comparison.

```
-- § Strict order implies non-strict by forgetting the margin
<ℝ→≤ℝ : {x y : ℝ} → x <ℝ y → x ≤ℝ y
<ℝ→≤ℝ {x} {y} x<y = record
 { leReal = λ δ δpos →

      in
      ≤ℚ-trans xn≤yn yn≤yn+δ)
  }
```

Law 23.4: Equivalence forces non-strict order

Representative equivalence forces non-strict order because eventual distance bounds eliminate any persistent asymptotic gap. The resulting order law therefore remains invariant under replacement by an equivalent Cauchy representative.

```
  -- § Equivalence implies ≤ℝ
  ≃ℝ→≤ℝ : {x y : ℝ} → x ≃ℝ y → x ≤ℝ y

       distℚ≤ϵ→x≤y+ϵ (seq x n) (seq y n) ϵ (<ℚ→≤ℚ (conv n N≤n)))
   }
```

Transitivity of Strict Order

Strict asymptotic separation must compose whenever two positive margins occur in sequence. The remaining freedom that an intermediate witness could block composition is eliminated, forcing strict order to survive transitive chaining.

Law 23.5: Strict order is transitive

Witness margins compose after controlled shrinking. Quartering eliminates overflow in the combined error budget and forces one surviving positive margin for the composite comparison.

Congruence of Strict Order under $\simeq_{\mathbb{R}}$

If strict order depends on which representative carries it, it is not an order on real numbers—it is merely an order on sequences. The Cauchy quotient annihilates any comparison that cannot survive a representative swap. The proof below shows that strict order does survive, by quartering the original witness gap and absorbing the equivalence corrections into the margin.

Strict order must survive elimination of representative choice, otherwise it would not descend from Cauchy data to the real quotient. That dependence is removed by transporting a strict witness across equivalence on both sides while preserving a positive asymptotic gap.

Constraint: The positive gap ε_0 that witnesses $x <_{\mathbb{R}} y$ must remain strictly positive after both sides are perturbed by representative change.

Elimination: Quarter ε_0 into four budgets, spend two on transporting through $x \simeq x'$ and $y \simeq y'$, and retain a strictly positive remainder as the new witness. Any budget that fails to leave a positive remainder is annihilated by the sandwich $\alpha + \beta < \varepsilon < \varepsilon_0$; the quartering is the unique surviving allocation.

Consequence: $<_{\mathbb{R}}$ is well-defined on the Cauchy quotient. No comparison can be fabricated or destroyed by representative choice.

Law 23.6: Strict order is invariant under equivalence

The witness margin survives both equivalence corrections by repeated quartering. This eliminates representative drift while preserving a strictly positive asymptotic gap.

Reflexivity of $\leq_{\mathbb{R}}$

Any admissible asymptotic order must retain self-comparison. The positive margin only relaxes the comparison further, so any failure of reflexivity would contradict the order structure already forced on representatives.

Law 23.7: Non-strict order is reflexive

Reflexivity is forced because every positive margin preserves the same sequence pointwise. Self-comparison must therefore hold on every tail with no residual freedom.

```
-- § Reflexivity of ≤ℝ
≤ℝ-refl : (x : ℝ) → x ≤ℝ x
≤ℝ-refl x = record
```

```
{ leReal = λ ϵ ϵpos →
  zero , (λ n _ →
   ≤ℚ-add-nonneg-right (seq x n) ϵ (<ℚ→≤ℚ ϵpos))
}
```

Transitivity of $\leq_{\mathbb{R}}$

Eventual upper bounds are forced to compose across an intermediate real. The only remaining work is to control the accumulated margin so that the composite comparison still fits inside the requested tolerance.

Law 23.8: Non-strict order is transitive

Two eventual $\varepsilon/4$ bounds are forced into one eventual ε bound. Associativity eliminates ambiguity in how the margins accumulate along the composite comparison.

Antisymmetry of $\leq_{\mathbb{R}}$

Mutual asymptotic domination must collapse to equality of reals. If two representatives eventually bound each other at every positive margin, no residual distance can survive in the quotient.

Law 23.9: Mutual non-strict order forces equivalence

Two-sided eventual bounds force asymptotic distance below every positive margin. What survives is exactly equivalence of the underlying Cauchy representatives.

```

Congruence of $\leq_{\mathbb{R}}$ under $\simeq_{\mathbb{R}}$

Strict order has been saved. But if non-strict order cannot survive the same representative swap, the ordered-field structure is only half-built: reflexivity and transitivity would apply to sequences, not to reals. The rescue is simpler than for strict order, because $\leq_{\mathbb{R}}$ can be transported by composing with the equivalence-induced bounds that already exist.

Non-strict order must also survive elimination of representative choice, otherwise order would not descend to the real quotient. The only admissible transport is composition with the equivalence-induced order bounds already forced above.

Constraint: $\leq_{\mathbb{R}}$ must be well-defined on the Cauchy quotient: if $x \simeq x'$ and $y \simeq y'$, then $x \leq y$ implies $x' \leq y'$.

Construction: Chain $x' \leq x$ (from $x \simeq x'$), $x \leq y$ (given), and $y \leq y'$ (from $y \simeq y'$) via transitivity. Any path that fails to compose through the equivalences is eliminated; the transitive chain is the only surviving route.

Consequence: $\leq_{\mathbb{R}}$ descends to the quotient. Together with $<_{\mathbb{R}}$, the full order structure is representative-independent.

Law 23.10: Non-strict order is invariant under equivalence

The congruence law is forced by composing equivalence-induced bounds on the left and right. No additional order data survives elimination.

```
-- § Non-strict order respects ≃ℝ
≤ℝ-resp-≃ℝ : {x x' y y' : ℝ} → x ≃ℝ x' → y ≃ℝ y' → x ≤ℝ y → x' ≤ℝ y'

 in
 ≤ℝ-trans (≤ℝ-trans x'≤x x≤y) y≤y'
```

Right Additive Monotonicity of $\leq_{\mathbb{R}}$

An ordered ring in which addition can reverse an inequality is useless for the invariant chain: every spectral bound, every additive transport depends on monotonicity under addition. Adding a common term to both sides of an inequality must not destroy the comparison, or the later additive transport laws for the derived constants collapse.

Right addition must preserve asymptotic order. Once addition has been forced on reals, adjoining the same summand on the right cannot create a new comparison failure.

Constraint: $x \leq y$ must imply $x + z \leq y + z$ for every real z.

Construction: Lift pointwise rational monotonicity through $+\mathbb{Q}$-mono-$\leq$-right, then use ε-margin associativity to eliminate ambiguity in the placement of the surviving margin. Any alternative placement breaks the tail bound.

Consequence: Both right and left monotonicity are forced, completing the twelve-law ordered-field scaffold.

Law 23.11: Right addition preserves non-strict order

Right monotonicity is forced by pointwise rational monotonicity. Associativity eliminates ambiguity in the placement of the surviving ε-margin.

```

Left Additive Monotonicity of $\leq_{\mathbb{R}}$

Left addition must preserve the same asymptotic order. This removes any residual asymmetry between the two inputs of addition at the level of order transport.

Law 23.12: Left addition preserves non-strict order

Left monotonicity is forced by the same rational order law, now applied through the left summand. Associativity again eliminates ambiguity in the placement of the surviving margin.

The numerical machinery is in place. Natural numbers, integers, rationals, reals, order, distance, scaling, and spectral operators have all been forced from the surviving structure rather than imported from outside it. The full language required to evaluate K_4 quantitatively is established—and every law in that language is a theorem, not a postulate. This is the methodological extreme the eliminative discipline demands: the arithmetic that measures the survivor is itself a consequence of the survivor.

The final step is assembly. The invariants already derived must be gathered, their values evaluated, and the logical closure of the chain confirmed.

Part VI

Derived Constants of K_4

The arithmetic, spectral theory, and evaluation apparatus built in Part V constitute the machinery needed to extract numerical values from K_4's combinatorial invariants. This part performs that extraction—and then closes the loop.

Nothing new is assumed. The vertex count, edge count, Euler characteristic, and Laplacian eigenvalues of K_4 are assembled into a verified computation record. Each entry is a definitional equality closed by the Agda type system. The numerical values that result—including the graph evaluation $\mathcal{C} = 137$—are consequences of the structure derived in Parts I through IV, evaluated by the arithmetic derived in Part V. Not one import, not one postulate, not one adjustable parameter.

The invariant record is then proved to be a singleton: any two admissible records must agree on every field. This is the sharpest conclusion the eliminative method can deliver—not merely that K_4 exists, but that its invariant description is the only one that survives.

Two further results close the derivation. The measurement kernel establishes that any apparatus capable of binary discrimination already presupposes the distinction D_0 from which the chain began—an independent route to the same root, sharing no lemma with the eliminative chain. And the final theorem proves that every admissible invariant record already consumes a distinction, closing the loop: $D_0 \Longrightarrow K_4 \Longrightarrow \text{record} \Longrightarrow D_0$.

The reader should keep two claims sharply apart. The theorem-level claim is internal to the formal system: given the derivation already established, these equalities reduce and these numbers compute. This claim is proved here. Whether these numbers have further significance is an interpretive question that belongs outside the formal chain.

Chapter 43

Natural-Number Division Infrastructure

The combinatorial laws of K_4 require exact natural-number division, yet the safe base environment does not provide the needed machinery. This chapter therefore fixes the minimal arithmetic infrastructure that survives the safety constraints and still forces every later combinatorial count to remain mechanically decidable.

Two primitives are needed: a greatest common divisor that terminates on all inputs, and an integer division that recovers exact quotients when they exist. Both are fuel-bounded—the recursion carries an explicit natural-number counter that decreases at each step—because the safe base environment provides no other termination discipline. This is not a design choice; it is forced by the absence of well-founded recursion in the minimal base. The fuel bound is always the sum of the two inputs, which is enough because each Euclidean subtraction step reduces that sum by at least one.

Constraint: Termination of the Euclidean algorithm on arbitrary naturals requires an explicit fuel counter in the safe base.

Construction: Without structural recursion on an explicit fuel counter, no terminating implementation of the Euclidean algorithm survives the safe base. The only surviving form is a three-argument gcd-fuel recurrence that subtracts the smaller input from the larger at each step, consuming one unit of fuel, and a div-fuel recurrence that counts how many times the divisor fits.

Consequence: Both primitives are total and structurally decreasing in fuel. Every downstream combinatorial identity reduces to refl once the fuel evaluates.

... | true = refl
... | false = refl

-- § GCD with canonical fuel
gcd : ℕ → ℕ → ℕ
gcd m n = gcd-fuel (m + n) m n
```

Once the GCD engine is in place, the only remaining primitive is exact division. A rational quotient n/d must be decomposable into a whole-number part whenever d divides n; otherwise the correction fractions in the companion module would remain opaque to computation. Division is again fuel-bounded, counting how many times the divisor can be subtracted before the remainder drops below it.

Canonical Quotient Data and Reduced Witnesses

The quotient layer cannot remain hidden behind decimal notation or behind the raw setoid. If a rational observable entered the theory with its numerator and denominator left implicit, the same presentation-noise that earlier chapters eliminated would quietly return at the arithmetic boundary. The rational layer must therefore expose its own surviving ledger.

Part IV already forced admissible observables to collapse to canonical base content. That pressure now reaches the quotient level. Every admissible rational observable must carry pointwise quotient data visible at the base, and any reduced witness that survives must be unique. The gcd-and-division infrastructure built above now extracts a reduced witness for every quotient class—including negative and zero classes—so the canonical normal form is globally available. What follows is therefore the full quotient-presentation layer: from the raw setoid lift through the divisibility engine to the final signed reduced form that every admissible rational observable is forced to carry.

Constraint: A rational observable may not hide its quotient structure behind the equality relation. If numerator and denominator remained observationally ambiguous, admissibility would collapse back into representation choice.

Construction: Any observable structure that hides its quotient fields behind the equality relation is eliminated by the admissibility constraint. The only surviving pathway lifts rational values into Set_ω, packages their explicit quotient data, and then lifts that presentation pointwise along admissible observables. Reduced witnesses are forced as positive numerator/denominator presentations together with coprimality, and uniqueness is forced by the quotient fields themselves. The same mechanism extracts a canonical reduction candidate from the raw fields by dividing numerator and denominator by their computed gcd.

Consequence: Every rational class now admits a signed reduced normal form—proved via the canonical-reduction-form theorem that splits on sign, reduces the magnitude through the gcd engine, and lifts the result through negation compatibility. The irreducible nonnegative sector, the zero class, and the negative classes are all closed. At the observable level, quotient fields are globally visible and any reduced witness is unique whenever it exists.

Quotient presentation and field uniqueness

Before reduction can begin, the rational type must expose its quotient fields as inspectable data. If a rational $q = n/d$ entered the theory opaquely—with the constructor fields hidden behind the setoid relation—then later admissibility tests would have nothing concrete to classify. The lift into Set_ω makes rational observables composable with the drift framework, and the presentation record simply reads off the constructor fields that already exist. The uniqueness lemma then eliminates any residual doubt: these fields are not a choice of presentation but the only surviving data.

```

Reduced witnesses and irreducibility

Once the quotient fields are visible and unique, the next question is sharper: when is a rational already in reduced form? The answer is forced by coprimality. A quotient n/d is *irreducible* when $\gcd(|n|, d) = 1$—when the numerator magnitude and the denominator share no factor beyond one.

A *reduced rational witness* makes this concrete. It records a natural numerator, a positive denominator, a proof that the rational equals this pair (up to definitional equality), and a proof that the pair is coprime. The uniqueness of reduced witnesses follows immediately from the uniqueness of quotient fields: if two reduced witnesses both present the same rational, their numerators and denominators must agree, because the fields are read from the same constructor.

This subsection also establishes the injectivity of the natural embedding $\mathbb{N} \hookrightarrow \mathbb{Z}$, which is needed to transport the numerator equality from the integer level down to the natural level.

Constraint: Two reduced witnesses for the same rational must agree on every component, otherwise "the" canonical form would not exist and downstream equational chains over reduced fractions would split into incompatible branches.

Construction: The witness type pairs a natural numerator and positive denominator with a coprimality proof. Uniqueness is forged by composing rational-fields-unique with fromℕℤ-injective, transporting the integer-level equality of numerators to the natural level.

Consequence: Every rational has at most one reduced presentation. The coprimality predicate is a unique-choice principle on $\mathbb{Q}$, and no covert second witness can perturb later denominator-tracking arguments.

Arithmetic lemmas and exact division

The reduction pipeline requires a corridor of small arithmetic facts—about subtraction, comparison reflection, packaging, and exact division—that would otherwise interrupt the flow of the main argument if proved inline. None of these is surprising. Each is a single-step verification that the safe base arithmetic behaves as expected under successor encoding.

The culmination of this corridor is the exact-division theorem: when d divides n, the fuel-bounded division recovers the quotient exactly. The proof proceeds by induction on the quotient q, showing that each subtraction step peels off one copy of d and that the accumulated fuel suffices for the recursion. This is the bridge between the raw division recurrence and the structured divisibility theory that follows.

   (div-one⁺ n))
```

At this point the corridor is narrow enough that the exact-division theorem can fire cleanly. The recurrence has no freedom left: each successful subtraction removes one copy of the divisor, and the surplus fuel merely witnesses that the recursion cannot stall too early.

Constraint: If div-fuel ever returned a value other than q on the input $q \cdot d +$slack, the entire denominator-tracking layer would collapse: every subsequent identity that pushes a divisor through a fuel-bounded recursion would require an extra side-condition.

Construction: The proof is a structural induction on q with the slack accumulator carried through the recursive call. The base cases close by refl; the step case exposes that one copy of d is consumed by a single subtraction and reroutes the slack into the next iteration, where the inductive hypothesis applies.

Consequence: Fuel never alters the result on exact multiples. The fuel parameter is a book-keeping device, not a semantic one, so all later quotient-preserving rewrites can ignore it without weakening the equality.

```

Positive divisibility theory

Before the gcd can serve the reduction pipeline, a divisibility language is needed. The raw statement "d divides n" must be a constructive record carrying the explicit quotient and the factorization proof, because later proofs need to extract that quotient for exact division. This is not a library convenience; it is forced by the absence of classical existentials in the safe base.

The $\mathrm{Divides}^+$ record captures exactly this: a positive divisor d, a quotient, and a proof that $n = q \cdot d$. From this single record, the section derives closure under addition, exact quotient extraction, quotient positivity, multiplication lift, right cancellation, order reflection, and subtraction—the complete divisibility algebra that the gcd engine needs.

Constraint: The gcd proofs require divisibility witnesses that carry computational content (the quotient), not merely propositional existence.

Construction: Any divisibility witness that lacks computational content—carrying only propositional existence without an explicit quotient—is eliminated by the downstream gcd proofs. The only surviving form is a record $\mathrm{Divides}^+\ \mathrm{d}\ \mathrm{n}$ with field $\mathrm{quotient}^+$ and factorization proof. Closure under $+$, $-$, multiplication, and cancellation follows.

Consequence: Every later divisibility argument reduces to record operations on $\mathrm{Divides}^+$. No ad hoc arithmetic witness is needed downstream.

The factor constraints above show that divisibility by a product forces each factor to be trivial when the product divides a single copy of one factor. This is the positive-integer analogue of the familiar number-theoretic fact that if $ab \mid b$, then $a = 1$. With this in hand, the machinery compares quotients: if d divides both m and n and $m \leq n$, then the stored quotient for m is at most the stored quotient for n.

GCD engine: common-divisor preservation, output divisibility, and positivity

The Euclidean gcd is defined, but a bare recurrence carries no force. Three properties must be forged before the gcd can serve the reduction pipeline:

Common-divisor preservation. Any positive integer that divides both inputs must still divide the output. This is the "upward" direction: known divisors survive the algorithm. The proof proceeds by mutual structural recursion, tracking divisibility through each subtraction step via the already established $\mathrm{divides}^{+}$-∸-≤ lemma.

Output divisibility. Conversely, if the gcd output is positive, it divides both inputs. This is the "downward" direction: the output itself is a common divisor. The proof is again by structural recursion on fuel, restoring divisibility through the subtraction witness at each step.

Positivity. Whenever at least one input is positive, the gcd output is also positive. This eliminates the degenerate case and ensures that the canonical reduction divisor is always well-formed as a positive natural.

Together, these three properties force the gcd to behave as the *greatest* common divisor in the usual sense: it divides both inputs, and every other common divisor divides it.

Constraint: The Euclidean recurrence alone does not determine the canonical reduction divisor. Without preservation of common divisors, output-divisibility, and positivity, the gcd output is a bare numeral with no algebraic role; the reduction pipeline downstream cannot type-check.

Construction: Mutual structural recursion over fuel-bounded subtraction steps forges three witnesses simultaneously. The preservation step transports any common divisor through the chain via $\mathrm{divides}^{+}$-∸-≤; the output-divisibility step restores divisibility by the same lemma read backward; the positivity step closes by case analysis on the inputs.

Consequence: The gcd inhabits the role of greatest common divisor: it divides both inputs and is divided by every other common divisor. Any rival reduction divisor that fails one of the three witnesses is annihilated by the corresponding lemma below.

The inductive core of the gcd engine is established: for any fuel level sufficient to reach termination, the positive output divides both inputs. The remaining step generalises this to the

canonical fuel formula $\mathrm{slack} + (m + n)$, which always provides enough iterations. This is the interface consumed by the rational reduction machinery above.

Canonical reduction candidate and divisibility

The gcd engine and the divisibility theory are both in place. The canonical reduction candidate is therefore forced: given a rational $q = n/d$, compute $g = \gcd(|n|, d)$, and define the reduced numerator as $|n|/g$ and the reduced denominator as d/g. The "candidate" is not a guess; it is the unique pair obtained by dividing out the maximal common factor.

Three properties must survive. First, the canonical divisor g is itself positive—forced by the gcd-positivity theorem on the positive denominator. Second, the ℕ-view of the divisor equals

the computed gcd—a bookkeeping identity that eliminates the successor-encoding detour. Third, the divisor divides both the numerator magnitude and the denominator—forced by the output-divisibility theorem already established for the gcd engine.

Constraint: The reduction candidate must be computable from the raw fields and must preserve the rational class up to $\simeq_{\mathbb{Q}}$. Any alternative decomposition would reintroduce presentation freedom.

Construction: Any reduction candidate not computable from the raw fields, or failing to preserve the rational class up to $\simeq_{\mathbb{Q}}$, is eliminated. The unique surviving candidate is canonical-reduction-divisor $= \mathrm{mk}\mathbb{N}^{+}(\gcd(|n|, d) - 1)$. The numerator and denominator are then forced by exact division. Positivity, value agreement, and divisibility follow from the candidate's definition.

Consequence: The candidate is well-defined and the gcd divides both fields. The factorization and coprimality proofs that follow proceed from concrete divisibility witnesses.

Factorization, coprimality, and witness stabilization

The canonical reduction divisor now divides both the numerator magnitude and the denominator. The next forced step is to show that dividing out the gcd produces a coprime pair—so that the candidate is genuinely reduced—and that the entire candidate stabilizes on any input that is already reduced.

Factorization is read directly from the exact-division infrastructure: since the gcd divides both fields, exact division recovers the quotients, and the original fields are the product of quotient times divisor. Coprimality then follows by contradiction: any common divisor of the reduced pair would lift, through multiplication by the gcd, to a common divisor of the *original* pair that exceeds the gcd itself—which contradicts the maximality of the gcd.

Stabilization completes the picture. If the input is already irreducible, the gcd is 1, division by one leaves the fields unchanged, and the candidate collapses to the original witness. This guarantees that the reduction pipeline is idempotent: applying it twice yields the same result as applying it once.

Constraint: Without coprimality, the "reduced" candidate might still hide common factors, and the uniqueness guarantee downstream would fail.

Elimination: Factor both fields through exact division; eliminate any putative common divisor by lifting it back through the gcd—where it is absorbed; eliminate instability by specializing to divisor = 1. The candidate survives all three tests.

Consequence: The canonical candidate is a genuine reduced pair. The reduced witness is idempotent. Every later reference to "the reduced form" is unambiguous.

The gcd machinery has confirmed that the canonical divisor is one, and the field-extraction lemma locks the numerator and denominator of the reduced witness to the original quotient fields. These are bookkeeping results—they do not change the mathematical content, but they allow every subsequent proof to refer to the reduced form without re-deriving the field correspondence each time.

The next step converts a reduced witness into a full irreducibility certificate. Once this is in hand, any rational that admits a reduced witness is provably in lowest terms, and no further simplification is possible.

Normal forms and sign handling

The canonical reduction machinery so far operates on magnitudes: it divides a natural numerator and a positive denominator by their gcd. But a rational number is not a magnitude—it carries a sign. The ReducedRationalForm record captures the quotient-level normal form for nonnegative classes, where the numerator is still a natural number and the equivalence is up to $\simeq_{\mathbb{Q}}$ rather than raw definitional equality. This weaker formulation is forced because gcd-reduction may change the concrete numerator and denominator while preserving the rational class.

For genuinely arbitrary classes including negative ones, a SignedReducedRationalForm extends the nonneg form by allowing the numerator to be an integer. The bridge between the two is the sign-transport infrastructure: negation preserves rational equivalence (-ℚ-resp-≃), and the magnitude of a negated embedded natural is still the original natural (magℤ-neg-fromℕℤ). These two facts together allow a negative class $(-n)/d$ to be reduced by first reducing $(+n)/d$ and then transporting the result through negation.

Constraint: Negative rationals cannot be reduced by the nonneg pipeline directly; their sign must be factored out, the magnitude reduced, and the sign restored.

Construction: Any normal form that fails to cover the negative sector is eliminated by the sign-transport constraint. The only surviving forms are ReducedRationalForm for the nonneg sector; SignedReducedRationalForm as the signed generalisation; reduced-form→signed as the canonical embedding; and -ℚ-resp-≃ plus magℤ-neg-fromℕℤ as the sign-transport lemmas.

Consequence: Every nonneg form lifts to a signed form. Every negative class is reduced by negation transport. The zero class is trivially nonneg. Together, these three cases cover all of ℚ.

 }
```

Global reduction theorems

The individual components—coprimality, factorization, sign handling, nonnegative witnesses—are all in place. What remains is to forge them into the global theorem: every rational class, regardless of sign, admits a canonical signed reduced form.

The route is forced. For nonnegative numerators, the factorization data is already available: the gcd divides both numerator magnitude and denominator, the candidate quotients are coprime, and the factorization record can be assembled outright. For negative numerators, the argument proceeds by negation transport: the positive representative $|n|/d$ is reduced first, and the result is then carried back through -ℚ-resp-≃ and magnitude-invariance of negation on embedded naturals. The zero class collapses immediately.

Constraint: Without a global theorem covering all three sign cases, the bridge chapter would need ad hoc case splits at every correction fraction.

Construction: Each sign case is handled and eliminated in turn: the nonnegative factorization is packaged into CanonicalReductionFactorization, the quotient-level ReducedRationalForm is derived, the lift to SignedReducedRationalForm closes the nonneg case, and the negative case is eliminated by reducing the negation and transporting the result. No sign case escapes.

Consequence: canonical-reduction-form is total on all of ℚ: zero, positive, and negative classes. The downstream companion modules may now invoke reduced quotient data without case analysis.

Observable quotient layer

The class-level reduction is complete: every rational carries a signed reduced form. But the invariant chain does not touch rationals in isolation. It touches *admissible rational observables*—functions from drift states into $\mathbb{Q}$ that already survive the admissibility filter. If quotient data were not lifted pointwise along these observables, the bridge chapter would be forced to re-derive the presentation at every call site, and the uniqueness guarantee would dissolve into ad hoc casework.

The lift is immediate. An admissible rational observable already assigns a rational value at each drift state. Reading off the constructor fields at each state gives the canonical pointwise presentation; the uniqueness of those fields then propagates pointwise. Reduced witnesses are similarly lifted: a reduced observable carries a reduced witness at every state, and whenever two such witnesses exist, they agree pointwise because the class-level uniqueness theorem already forces agreement field by field.

Constraint: If quotient fields were not globally visible on admissible observables, the correction fractions would lack a canonical numerator/denominator decomposition at each measurement point.

Construction: Any observable layer that fails to expose quotient data pointwise is eliminated by the admissibility constraint. The only surviving form lifts RationalPresentation and ReducedRationalWitness pointwise along AdmissibleRationalObservable, inheriting uniqueness from the class-level theorems.

Consequence: The bridge chapter may now invoke quotient data and reduced witnesses at any drift state without re-deriving them. The observable quotient layer is closed.

Chapter 44

K_4 Forced Constants Layer

Once the simplex cardinality is fixed at $V = 4$, every combinatorial constant attached to K_4 is already determined. This chapter eliminates parameter freedom by computing edge counts, face counts, spectral constants, and cycle data directly from that forced cardinality, with each law collapsing to definitional equality.

That rigidity must not be overstated. Two different kinds of sentence appear in what follows, and they answer to different standards.

The first kind is theorem. A theorem here is an internal statement of the formal development: a count, spectrum, or equality that Agda closes by reduction. When this chapter proves that a quantity on K_4 is 4, or 6, or 137, the claim is purely structural. It says only that these numbers are forced by the previously derived object.

The second kind is interpretation. Interpretation begins only when one asks whether a formally forced invariant should be read as a quantity in an external theory. That move is not part of the theorem. It is a separate act of comparison between the formal survivor and an external framework.

Constraint: The numerology objection gains force precisely when theorem and interpretation are allowed to blur. If a computed invariant is described as externally significant before the formal status of the computation is fixed, the reader can rightly suspect that the target meaning guided the construction.

Construction: Any methodology that blurs the boundary between theorem and interpretation is eliminated: it reintroduces the numerology objection. The only surviving discipline keeps the registers separate. First the invariant is computed as a theorem internal to the K_4 record. Only afterward may a companion volume state the possible external reading of that already-fixed value. In this chapter, proofs close in the first register; external comparisons belong to *Form*.

Consequence: The formal content of the chapter stands or falls independently of any downstream interpretation. If an interpretation later fails, the theorem remains proved. If an interpretation later succeeds, it succeeds because it reads a pre-existing invariant rather than because the invariant was engineered to fit it.

Simplex invariants

The first layer fixes the bare tetrahedral invariants forced by $V = 4$. Edge count, face count, degree, and Euler characteristic are not introduced independently; each is the unique value surviving the standard simplex formulas.

Constraint: The four primary tetrahedral invariants E, F, deg, χ must be functions of V alone — otherwise an additional parameter would enter the K_4 ledger and the singleton claim downstream would fail.

Construction: Each invariant is defined by the standard simplex formula in V. With $V = 4$ substituted, the closed values $E = 6$, $F = 4$, deg $= 3$, $\chi = 2$ are discharged by refl. The match to the abstract simplex-* definitions of Tier 5 is sealed by the same computational equality.

Consequence: Each of V, E, F, deg, χ is invariant under $\mathrm{Aut}(K_4)$ — the formulas depend only on V, and V is the cardinality of the vertex set — so any deviation would break the symmetry chain. They are therefore necessary observables.

```

Clifford and spectral constants

These constants are forced from the same combinatorial core, so no separate parameter enters. Clifford dimension, hierarchy exponent, and the discrete evaluation data are computed as rigid consequences of the already fixed K_4 profile.

Constraint: The Clifford and spectral constants must reduce to closed expressions in V, E, F, d, χ alone. An independent constant at this layer would reintroduce the freedom that the simplex layer just eliminated.

Construction: Clifford dimension is forged as 2^V, hierarchy exponent and discrete evaluation data as polynomial combinations of the simplex invariants. Each closed numerical value is discharged by refl.

Consequence: The constants κ, $\mathcal{C}$, and the Clifford dimension are invariant under $\mathrm{Aut}(K_4)$, since they are functions of V, E, F, d, χ alone and each of those is itself $\mathrm{Aut}(K_4)$-invariant. Any deviation would break the symmetry chain. They are therefore necessary observables.

```

K_4 aliases and cycle counts

This layer eliminates notation drift by tying all later aliases back to the same forced counts. The cycle data then record the remaining named invariants needed downstream, again with no freedom beyond the tetrahedral combinatorics already fixed.

Constraint: Notational drift across chapters could reintroduce ambiguity: vertexCountK4, K4-V, and K_4-vertices-count must all denote the same forced numeral, otherwise downstream rewrites along one alias would silently fail when stated against another.

Construction: Each alias is a one-line definitional equation pointing to the canonical name (vertexCountK4, edgeCountK4, faceCountK4, degree-K4, eulerChar-computed). The aliases are exposed for both ASCII and unicode notation. The simplex-evaluation alias simplex-eval-K4 closes by refl on 137.

Consequence: Every later chapter may use any alias for any invariant; substitution along the definitional equality is silent. Each of $V = 4$, $E = 6$, $F = 4$, $d = 3$, $\chi = 2$, and $\kappa = 8$ is invariant under $\mathrm{Aut}(K_4)$ — no vertex label appears in any of their defining computations. Any deviation would break the symmetry chain. They are therefore necessary observables.

Generation index exhaustion

The non-zero spectrum of $L(K_4)$ carries multiplicity $d = 3$. Three eigenmodes demand three indices, and the indices cannot be imported from outside: every label that ranks them must already be a K_4 invariant, or the ranking smuggles in foreign content. The question is therefore

not which labels to choose, but which labels survive the constraint that they live in the natural ranking interval $[1, d]$.

The atomic alphabet of K_4 is $\{V, E, F, d, \chi, \kappa\} = \{4, 6, 4, 3, 2, 8\}$. Of its six members, exactly two fall in $[1, d]$: $\chi = 2$ and $d = 3$. The remaining slot $\{1\}$ is realised by no atom, but by the unique atomic shortfall: $V \dot{-} d = F \dot{-} d = d \dot{-} \chi = 1$. Three independent atomic differences collapse onto the same value, and that value closes the interval.

Once the interval $[1, d]$ is closed by $(V \dot{-} d, \chi, d) = (1, 2, 3)$, no other strictly monotone triple of basis atoms in $[1, d]$ can occupy it—every alternative either repeats a value, leaves a gap, or exceeds d. The three eigenmode indices are therefore not chosen but forced within the basis.

Constraint: Three eigenmodes demand three distinct K_4-derived ranking labels in the interval $[1, d]$. No labelling that imports a non-K_4 value can pass the admissibility filter that rejects external content.

Elimination: The atoms above d (V, E, F, κ) cannot occupy any slot in $[1, d]$. The atoms inside $[1, d]$ are exhausted by χ and d. The only remaining slot $\{1\}$ admits exactly one K_4-derived value, realised by three coincident atomic differences $V \dot{-} d = F \dot{-} d = d \dot{-} \chi = 1$. Every other monotone triple either repeats a value or punctures the interval.

Consequence: The strictly monotone triple $(V \dot{-} d, \chi, d) = (1, 2, 3)$ is the unique enumeration of the eigenmode indices by K_4 atoms and atomic differences. Any companion identification of generation labels with these three indices reads a structure that is already forced; the labelling adds no freedom.

Both atomic shortfalls $d \dot{-} \chi$ and $\chi \dot{-} (V \dot{-} d)$ collapse to the same value $V \dot{-} d = 1$. This single shortfall is what closes the generation interval, and the equality is a theorem above. Any companion identification of the two transitions belongs to *Form*; the combinatorial statement is settled here.

Every combinatorial constant of K_4 is fixed by definitional equality: vertex count, edge count, face count, degree, Euler characteristic, spectral width, generation indices, and cycle data. The ledger is sealed. What remains is to show that these constants determine a unique formal representation record—that no second assignment of fields could survive the same constraints.

The forced invariants. At the theorem level, K_4 determines $V = 4$, $E = 6$, an eigenvalue ratio 3:1, and the graph evaluation $\mathcal{C} = 137$. None of these numbers were adjusted. Each is a definitional equality closed by the Agda type checker. Whether these values carry any downstream identification belongs to the companion volume. What remains is the uniqueness proof: whether any two admissible representations must agree on every field, or whether a rival could survive the same constraints. That proof is Chapter 45. The canonicity of $\mathcal{C} = 137$ as a derived invariant—including the proof that no alternative degree-≤ 3 formula reaches the same prime—is in the companion volume *Form*.

Chapter 45

K_4 Representation Theory

The admissible invariant representation of K_4 must be unique: otherwise the passage from graph invariants to represented quantities would reintroduce contingency. This chapter forces uniqueness by anchoring one field to the simplex cardinality and chaining every remaining field to previously fixed invariants until no representational freedom survives. The result—that every admissible record collapses to a single canonical object—is one of the five distinctive conclusions of the derivation. It is not merely that K_4 exists, or that its invariants are determined, but that the invariant record is a *singleton*: any two inhabitants of the record type must agree on every field.

Structural infrastructure

The infrastructure isolates the raw objects on which representation theory acts: vertices, basis states, adjacency, and neighbor summation. Nothing interpretive happens here; the section fixes the combinatorial carrier that every later representation claim must respect.

Constraint: Without an enumerated vertex type, an explicit adjacency function, and a Kronecker basis, every representation claim about K_4 would be parametrised over an unfixed carrier and lose its singleton status.

Construction: $\mathrm{K4Vertex}$ is forged as the four-constructor type $\{v_0, v_1, v_2, v_3\}$, $\mathrm{adjacent}$ as a pattern-matched complete graph minus the diagonal, δ as the Kronecker delta, and $\mathrm{sum\text{-}neighbors}$ as the graph-Laplacian action. Each function is total and decidable by construction.

Consequence: The carrier is fully determined: four vertices, six edges, no auxiliary slack. Every later representation lemma operates on this fixed carrier, and the auxiliary lemma $\mathrm{cover\text{-}necessary}$ demonstrates that the eliminator schema cannot be weakened without producing the standard $\perp$.

Vertex-invariance laws

K_4 is vertex-transitive, so any observable defined purely from adjacency data must ignore the choice of vertex label. These laws remove label dependence before any downstream interpretation is attached.

Constraint: If a function on K_4 depended on which vertex was chosen as v_0, it would not be an automorphism invariant and could not feature in the singleton record. Vertex-transitivity has to be discharged at the type level, not assumed in the prose.

Construction: Each law is a finite case-split over the four vertices, closed by refl. The adjacency row sum collapses to degree-K4 for every vertex; each basis state has total weight 1 for every vertex. The proofs are computational and exhaustive.

Consequence: Every later representation argument may use vertex transitivity as a pre-discharged fact. No covert label dependence can leak into the canonical record.

```
-- § Adjacency row sum equals vertex degree
law-adjacency-degree : (v : K4Vertex) →
 adjacent v v₀ + adjacent v v₁ + adjacent v v₂ + adjacent v v₃ ≡ degree-K4

```

The representation record

A invariant representation that floats freely above its graph would reintroduce contingency at the worst possible moment: after every graph invariant has been locked down. The record below eliminates that risk by packaging 17 unknowns with exactly one anchor (dim $\equiv V$) and 16 directed chain constraints. Once the anchor connects to K_4, every remaining field is forced to exactly one value through a rigid directed chain: dim fixes n-spatial, which fixes n-temporal, which fixes every subsequent field.

Constraint: Every record field must be uniquely determined by the K_4 anchor; no field may carry independent freedom.

Construction: Any record with fewer than 17 fields fails to cover the invariant chain; any record with an anchor weaker than dim ≡ vertexCountK4 leaves representational freedom alive. The only surviving structure packages 17 fields with 1 anchor (dim ≡ vertexCountK4) and 16 chained equalities. Each equality pins one field to a formula in previously fixed fields.

Consequence: The record is rigid: any admissible inhabitant is fully determined by the anchor alone. This is proved in the sections that follow.

```

Existence: the canonical witness

A record type with constraints is vacuously consistent until an inhabitant is exhibited. Without a witness, the forcing chain is a theorem about nothing. Existence is witnessed by the canonical

assignment obtained from the forced constants. Each proof closes by refl because the assigned values are not guesses; they are exactly the normal forms already determined by the constraint chain.

Constraint: The 17 fields and 16 chained equalities must be simultaneously satisfiable.

Construction: Each field is assigned its forced value (4, 3, 1, 6, 4, 2, 137, ...) and every constraint proof closes by refl—no alternative assignment survives the chain.

Consequence: The representation is inhabited. Combined with uniqueness, this makes it a singleton.

```

```

Determination: the forcing chain resolves every field

Existence shows the record is inhabited. But an inhabited record with 17 fields could still harbour hidden freedom if some fields were underdetermined by the constraints. The forcing chain eliminates that possibility: for any admissible representation r, each field is compelled to a unique natural number by walking outward from the anchor.

For any admissible representation, each field is forced to a specific value. The argument walks outward from the anchor, eliminating one degree of freedom per constraint until the entire record is rigid.

Constraint: Every field of every admissible representation must evaluate to the same number; otherwise representational freedom survives.

Construction: Start from dim $\equiv 4$ (the anchor). Each subsequent field is forced by eliminating every alternative: n-spatial $\equiv 3$ via cg-deg, then n-temporal $\equiv 1$ via cg-temporal, and so on through all 17 fields. No degree of freedom survives the chain.

Consequence: The representation is not just inhabited but rigid. Every field of every admissible representation evaluates to exactly one value.

Uniqueness: any two representations agree

Existence alone leaves a lethal gap: if two distinct representations of K_4 could coexist, the derived invariants would depend on which representation was chosen, and no structural criterion could distinguish them. Uniqueness closes that gap. Since ForcedValues pins every field of every admissible representation to the same normal form, any two representations must agree field by field. Singletonhood is therefore proved, not declared.

Constraint: Two admissible representations r_1, r_2 must agree on every field, or representational contingency survives.

Construction: For each field, chain F_1.field-is-k with sym F_2.field-is-k to eliminate any divergence between r_1.field and r_2.field.

Consequence: The invariant representation of K_4 is a singleton. No alternative survives.

Singleton: the representation has exactly one inhabitant

The preceding section proves that any two admissible representations agree on all 17 data fields. But data-field agreement is not yet record equality. The record $\mathrm{K4Record}$ also carries 16 proof fields—each of type $n \equiv m$ for specific natural numbers. If two proofs of the same natural-number equation could differ, then two representations with identical data could still diverge on the proof layer, and the singleton claim would harbour invisible slack.

Under $-\mathrm{without\text{-}K}$, uniqueness of identity proofs is not given for free. It must be derived. The route is Hedberg's theorem: any type with decidable equality satisfies UIP. Natural numbers have decidable equality by induction. Therefore every proof $p : m \equiv n$ on $\mathbb{N}$ is uniquely determined. Once the proof fields are locked, record eta forces full propositional equality.

Constraint: If two proofs of the same ℕ-equation could differ, the representation would fork at the proof layer even after the data layer is fixed.

Elimination: Decidable equality on ℕ by mutual recursion eliminates undecidable cases. Hedberg's theorem extracts a constant endomorphism on identity proofs from the decision procedure, eliminating all non-canonical retracts. Corollary: ℕ-UIP—no two distinct proofs of the same equation survive. Record-level singleton: transport every data field of an arbitrary representation to its forced value using ForcedValues, apply ℕ-UIP to eliminate all proof-field divergence, close by record eta.

Consequence: The invariant record of K_4 has propositionally exactly one inhabitant. The singleton is not 17 separate coincidences stitched together by convention. It is a single theorem: K4Record-singleton.

Cross-constraints: inter-layer consistency

The forcing chain is stratified into graph, algebraic, spectral, and combinatorial layers, but those layers cannot diverge. These cross-constraints eliminate inter-layer freedom by showing that values forced in one layer coincide exactly with the values demanded in the others.

Constraint: If a value forced in the graph layer disagreed with the corresponding value forced in the spectral or combinatorial layer, the singleton claim for K_4 would split into incompatible variants and the canonical record would not be unique.

Construction: The module CrossConstraints forges six bridge equalities, one per pair of layers. Each is discharged by refl on the canonical record, so the layers agree by computation rather than by stipulation.

Consequence: The four layers form a single rigid system. Any later attempt to vary a constant in one layer immediately violates one of the six bridge equalities and is shut out at the type level.

Constraint derivation: from named invariants to canonical witness

Every K4Record field is forced directly from named K_4 invariants. Bare numerals disappear from the assignment layer, and each proof closes by refl because the chain formulas are exactly the definitions of the named invariants they invoke.

Constraint: If even one record field were assigned by a bare numeral rather than by a named invariant, the assignment would carry a hidden choice and the singleton claim would collapse: a second canonical witness with a different numeral could be constructed without contradiction.

Construction: The module ConstraintDerivation chains every field through named invariants (degree-K4, vertexCountK4, edgeCountK4, ...). Each derivation law closes by refl because the chain formula coincides definitionally with the named invariant it invokes.

Consequence: The assignment layer carries no free numerals. Every field of K4Record is the unique value forced by the named invariants, and the canonical witness is therefore the unique inhabitant of the record type.

Represented quantities as computable K_4 invariants

The formal relation between graph invariants and the representation record is exact. Each represented quantity is a computable function of K_4 data: the output of the graph computation is exactly the value carried by the representation chain. Whether a given represented quantity should also be read as a measured observable remains a separate interpretive question.

Representation Completeness

The record built below is already rigid once one enters it. But the stronger pressure comes from outside. If there were two admissible ways to inhabit the same K_4 invariant spine, then the constants would not be observables forced by structure; they would be artifacts of representational wording. That would collapse the claim at the final step. The graph would still survive, but the

bridge into measurement would fork, and every numerical coincidence could be dismissed as notation. This fork must be shattered.

Constraint: Any admissible invariant representation of K_4 must preserve the named invariant chain already fixed: vertex count, edge count, face count, Euler characteristic, spectral data, and the derived observables assembled from them. No representational wrapper may introduce additional degrees of freedom while claiming to describe the same structure.

Construction: The module $\mathrm{RepresentationComplete}$ takes any admissible K_4 representation r as parameter and constructs, for every observable field, an equality witness identifying its value on r with the value on the canonical record. Each witness is built directly from the $\mathrm{ForcedValues}$ chain laws of r via projection; no auxiliary lemma intervenes.

$$\mathrm{RepresentationComplete} : (\text{admissible representation of } K_4) \to (\text{field-wise equality with the canonical } K4Recor$$

Consequence: With $\mathrm{RepresentationComplete}$ inhabited, the formal bridge asserts not that one chosen representation works, but that every admissible representation already coincides with the canonical record on every named invariant. Any later empirical reading must therefore attach to the unique formal record rather than to a convenient encoding chosen after the fact.

Local graph observables

The first block isolates the vertex-local computations: row sums, propagation directions, and the basis witness showing that the row sum equals the degree. That keeps the local layer visible before the global quantities are assembled from it.

```
-- § Represented quantities as computable K4 functions
module K4Quantities where

-- § Adjacency row sum at each vertex
adjacency-row-sum : K4Vertex → ℕ
adjacency-row-sum v =
 adjacent v v0 + adjacent v v1 + adjacent v v2 + adjacent v v3

-- § Row sum is vertex-uniform and equals degree
adjacency-row-sum-is-degree : (v : K4Vertex) → adjacency-row-sum v ≡ degree-K4
adjacency-row-sum-is-degree = law-adjacency-degree

-- § Each row sum propagates independently (basis property)
adjacency-row-sum-independent : (u v : K4Vertex) →
 sum-neighbors (K4-basis u) v ≡ adjacent v u
adjacency-row-sum-independent = law-basis-spreads
```

Global quantities built from the local layer

Once the local observables are fixed, the rest of the derived quantities are short global computations. Splitting them into a second block mirrors the earlier chapters, where constructors come first and packaged consequences follow afterward.

```

edge-tally : ℕ
edge-tally = edgeCountK4
```

Observable representation and closure

The representation is rebuilt entirely from computed observables. This removes the last appearance of ad hoc assignment: every field is a graph-theoretic computation on K_4, and every constraint reduces to refl because the defining formula already is the required computation.

Constraint: The named-invariant derivation removed bare numerals, but a residual asymmetry could still hide in the order in which fields are written. Closure demands that the observable representation and the canonical representation coincide *definitionally*, not merely propositionally.

Construction: observable-rep is forged as a K4Record whose every field is a computation on the fixed carrier (vertexCountK4, edgeCountK4, ...). The closure lemma observable-is-canonical asserts observable-rep ≡ canonical-rep and is discharged by a single refl.

Consequence: Computed and stipulated representations are the same term up to definitional equality. The canonical witness is no longer "one possible assignment" but the unique normal form of any admissible assignment.

```
-- § K4Record from computed quantities (no bare numerals)
observable-rep : K4Record
observable-rep = record
 { dim          = vertexCountK4

 ; ph-frac-den = refl
 }

-- § Closure: observable-rep IS canonical-rep (definitional equality)
observable-is-canonical : observable-rep ≡ canonical-rep
observable-is-canonical = refl
```

The observable principle

The observable principle removes the final semantic slack: an observable on K_4 is exactly an automorphism-invariant computable function. Because K_4 is vertex-transitive, every local observable must be uniform across vertices, while every global observable is already fixed by graph-isomorphism invariance on the named combinatorial data.

Constraint: A free numeric layer above the named invariants would reintroduce the descriptive freedom that the singleton chapter eliminated. The observable principle has to close

the gap between "computable function on K_4" and "forced invariant".

Construction: The local layer is forged as $\Sigma\,(K_4\text{Vertex} \to \mathbb{N})$ IsK4Invariant, requiring uniformity across vertices. The global layer is the four-constructor enumeration GlobalObservable together with its canonical evaluation map. The complete observable type is their disjoint union.

Consequence: Every admissible observable is either a vertex-uniform local function or one of four global codes. The space of observables is exhausted at the type level; no fifth class can be smuggled in.

Observable types and invariance

```
-- § K₄ vertex-level invariance
IsK4Invariant : (K4Vertex → ℕ) → Set
IsK4Invariant f = (v w : K4Vertex) → f v ≡ f w

-- § Local observable: vertex function + uniformity proof
LocalObservable : Set
LocalObservable = Σ (K4Vertex → ℕ) IsK4Invariant

-- § Global admissible observables collapse to four canonical codes.
data GlobalObservable : Set where
 go-boundary go-spectral go-complement go-edges : GlobalObservable

eval-global-observable : GlobalObservable → ℕ
eval-global-observable go-boundary = boundary-count
eval-global-observable go-spectral = spectral-euler-product
eval-global-observable go-complement = complement-degree
eval-global-observable go-edges = edge-tally

-- § Complete observable type
Observable : Set
Observable = LocalObservable ⊎ GlobalObservable

-- § Every invariant function has a unique value, independent of vertex
invariant-value : (f : K4Vertex → ℕ) → IsK4Invariant f → ℕ
invariant-value f _ = f v₀

invariant-any-vertex : (f : K4Vertex → ℕ) → (inv : IsK4Invariant f) →
 (v : K4Vertex) → f v ≡ invariant-value f inv
invariant-any-vertex f inv v = inv v v₀

observable-value : Observable → ℕ
observable-value (inj₁ (f , inv)) = invariant-value f inv
observable-value (inj₂ g) = eval-global-observable g
```

Local observable witnesses

The next block shows the local pattern once: define the observable, prove vertex-uniformity, then read off its canonical value. Keeping that pattern separate prevents the proof witness from disappearing inside the later list of global observables.

```
-- § Adjacency-row-sum is a local observable
adjacency-row-sum-invariant : IsK4Invariant adjacency-row-sum
```

```
adjacency-row-sum-invariant v w =
 trans (adjacency-row-sum-is-degree v) (sym (adjacency-row-sum-is-degree w))

adjacency-row-sum-observable : LocalObservable
adjacency-row-sum-observable = adjacency-row-sum , adjacency-row-sum-invariant

-- § Observed value is degree = 3
adjacency-row-sum-observed-value : invariant-value adjacency-row-sum adjacency-row-sum-invariant
 ≡ degree-K4
adjacency-row-sum-observed-value = refl

-- § Adjacency row sum is a local observable
adj-row : K4Vertex → K4Vertex → ℕ
adj-row v w = adjacent v w

adj-row-sum-invariant : IsK4Invariant (λ v →
 adj-row v v₀ + adj-row v v₁ + adj-row v v₂ + adj-row v v₃)
adj-row-sum-invariant v w =
 trans (law-adjacency-degree v) (sym (law-adjacency-degree w))
```

Global observable witnesses

An unrestricted numeric container for the global layer reintroduces descriptive freedom. A natural number written down after the graph is fixed does not become a global observable by being named. The admissibility filter therefore has to close the space itself. Only four primitive global classes survive: boundary, spectral, complement, and edges. Everything else in the downstream discussion is either a value of this basis or a derived ledger invariant, not a fifth admissible global observable.

Constraint: A global observable must be presentation-independent and forced by the invariant spine of K_4. If the global layer were identified with arbitrary naturals, the observable principle would fail exactly where it is supposed to become strongest.

Construction: The global sector is forged as a finite enumeration GlobalObservable with exactly four constructors — boundary, spectral, complement, edges — paired with a total evaluation map eval-global-observable into the already forced graph quantities. The exhaustiveness lemma global-observable-exhaustive is then discharged by case-split, witnessing that the four codes saturate the type by definition.

Consequence: Any later proposal of a fifth primitive global observable is shut out at the type level: it would have to inhabit GlobalObservable and would therefore reduce to one of the four constructors. The space of primitive global observables is closed, finite, and exhausted by those four codes.

```
-- § Global observables (invariant by construction)
obs-boundary : Observable
obs-boundary = inj₂ go-boundary

obs-spectral : Observable
obs-spectral = inj₂ go-spectral

Chapter 46

K_4 Vertex Permutations

The automorphism group $\mathrm{Aut}(K_4) \cong S_4$ acts on the four vertices by permutation. For a complete graph, every bijection is a graph automorphism—adjacency depends only on distinctness, and bijections preserve distinctness. The group acts 2-transitively: for any two ordered pairs of distinct vertices, some permutation maps one to the other.

This chapter builds the formal infrastructure. The strategy re-uses the permutation machinery already proven for EndoCase—transpositions, involutivity, transitivity—by lifting it through an explicit bijection K4Vertex ↔ EndoCase. No case table is re-proved; the 64-entry involution table for swapEndo does all the work.

Constraint: The permutation group must act on K4Vertex with full bijectivity proofs, not merely produce functions.

Construction: Any permutation structure that lacks full bijectivity proofs is eliminated by the round-trip requirement. The only surviving form is a record K4Perm packaging transport and inverse with round-trip laws. Transpositions and compositions inherit these from EndoPerm. Decidable equality on K4Vertex provides the case analysis that the adjacency-preservation proof requires.

Consequence: Any ℕ-valued function on vertex pairs that is invariant under all K4Perm has a single uniform value on all off-diagonal entries. This is the core tool the forced-propagation elimination will use.

Vertex bijection

The bijection between K4Vertex and EndoCase maps constructors to constructors and round-trips in both directions.

```
k4-to-endo : K4Vertex → EndoCase
k4-to-endo v₀ = case-constL
k4-to-endo v₁ = case-constR
k4-to-endo v₂ = case-id
k4-to-endo v₃ = case-dual

endo-to-k4 : EndoCase → K4Vertex
endo-to-k4 case-constL = v₀
```

```
endo-to-k4 case-constR = v₁
endo-to-k4 case-id     = v₂
endo-to-k4 case-dual = v₃

k4-endo-k4 : (v : K4Vertex) → endo-to-k4 (k4-to-endo v) ≡ v
k4-endo-k4 v₀ = refl
k4-endo-k4 v₁ = refl
k4-endo-k4 v₂ = refl
k4-endo-k4 v₃ = refl

endo-k4-endo : (e : EndoCase) → k4-to-endo (endo-to-k4 e) ≡ e
endo-k4-endo case-constL = refl
endo-k4-endo case-constR = refl
endo-k4-endo case-id     = refl
endo-k4-endo case-dual = refl
```

Permutation record and lifting

A K4Perm is a bijection on K4Vertex: forward and inverse maps with round-trip proofs. The function liftPerm converts any EndoPerm into a K4Perm by conjugating through the vertex bijection.

```
record K4Perm : Set where
 field
  k4to     : K4Vertex → K4Vertex
  k4from : K4Vertex → K4Vertex
  k4-to-from : (v : K4Vertex) → k4to (k4from v) ≡ v
  k4-from-to : (v : K4Vertex) → k4from (k4to v) ≡ v

open K4Perm public

liftPerm : EndoPerm → K4Perm
liftPerm σ = record
 { k4to     = λ v → endo-to-k4 (eto σ (k4-to-endo v))
 ; k4from = λ v → endo-to-k4 (efrom σ (k4-to-endo v))
 ; k4-to-from = λ v →
   trans (cong (λ e → endo-to-k4 (eto σ e))
                 (endo-k4-endo (efrom σ (k4-to-endo v))))
         (trans (cong endo-to-k4 (eto-efrom σ (k4-to-endo v)))
                 (k4-endo-k4 v))
 ; k4-from-to = λ v →
   trans (cong (λ e → endo-to-k4 (efrom σ e))
                 (endo-k4-endo (eto σ (k4-to-endo v))))
         (trans (cong endo-to-k4 (efrom-eto σ (k4-to-endo v)))
                 (k4-endo-k4 v))
 }
```

Composition of two permutations inherits bijectivity from the components.

```
k4Perm-comp : K4Perm → K4Perm → K4Perm
k4Perm-comp σ τ = record
 { k4to     = λ v → k4to σ (k4to τ v)
 ; k4from = λ v → k4from τ (k4from σ v)
 ; k4-to-from = λ v →
   trans (cong (k4to σ) (k4-to-from τ (k4from σ v)))
         (k4-to-from σ v)
 ; k4-from-to = λ v →
   trans (cong (k4from τ) (k4-from-to σ (k4to τ v)))
         (k4-from-to τ v)
 }
```

Decidable equality and adjacency lemmas

Decidable equality on K4Vertex enables proofs that branch on whether two vertices coincide. It is forced by constructor discrimination: the four constructors are pairwise distinguishable.

```
K4-decEq : (v w : K4Vertex) → (v ≡ w) ⊎ (v ≢ w)
K4-decEq v₀ v₀ = inj₁ refl
K4-decEq v₁ v₁ = inj₁ refl

K4-decEq v₃ v₃ = inj₁ refl
K4-decEq v₀ v₁ = inj₂ (λ ())
K4-decEq v₀ v₂ = inj₂ (λ ())
K4-decEq v₀ v₃ = inj₂ (λ ())
K4-decEq v₁ v₀ = inj₂ (λ ())
K4-decEq v₁ v₂ = inj₂ (λ ())
K4-decEq v₁ v₃ = inj₂ (λ ())
K4-decEq v₂ v₀ = inj₂ (λ ())
K4-decEq v₂ v₁ = inj₂ (λ ())
K4-decEq v₂ v₃ = inj₂ (λ ())
K4-decEq v₃ v₀ = inj₂ (λ ())
K4-decEq v₃ v₁ = inj₂ (λ ())
K4-decEq v₃ v₂ = inj₂ (λ ())
```

Two structural facts about adjacent: it returns 0 on the diagonal and 1 on every off-diagonal pair. Together they say that adjacency in K_4 is exactly distinctness.

```
adj-self : (v : K4Vertex) → adjacent v v ≡ 0
adj-self v₀ = refl
adj-self v₁ = refl
adj-self v₂ = refl
adj-self v₃ = refl

K4-distinct-adj : (v w : K4Vertex) → v ≢ w → adjacent v w ≡ 1
K4-distinct-adj v₀ v₀ ne = ⊥-elim (ne refl)
K4-distinct-adj v₀ v₁ _ = refl
K4-distinct-adj v₀ v₂ _ = refl
K4-distinct-adj v₀ v₃ _ = refl
K4-distinct-adj v₁ v₀ _ = refl
K4-distinct-adj v₁ v₁ ne = ⊥-elim (ne refl)
K4-distinct-adj v₁ v₂ _ = refl
K4-distinct-adj v₁ v₃ _ = refl
K4-distinct-adj v₂ v₀ _ = refl
K4-distinct-adj v₂ v₁ _ = refl
K4-distinct-adj v₂ v₂ ne = ⊥-elim (ne refl)
K4-distinct-adj v₂ v₃ _ = refl
K4-distinct-adj v₃ v₀ _ = refl
K4-distinct-adj v₃ v₁ _ = refl
K4-distinct-adj v₃ v₂ _ = refl
K4-distinct-adj v₃ v₃ ne = ⊥-elim (ne refl)
```

Injectivity of any K4Perm follows from the round-trip law: compose with the inverse on both sides.

```
k4-injective : (σ : K4Perm) → (v w : K4Vertex) →
 k4to σ v ≡ k4to σ w → v ≡ w
k4-injective σ v w p =
 trans (sym (k4-from-to σ v))
       (trans (cong (k4from σ) p)
              (k4-from-to σ w))
```

Transitivity and 2-transitivity

The group acts 1-transitively: any vertex can be sent to any other by some permutation. The proof lifts endoPerm-send through the bijection.

```
k4Perm-send : (a a' : K4Vertex) → Σ K4Perm (λ σ → k4to σ a ≡ a')
k4Perm-send a a' =
 let ep = endoPerm-send (k4-to-endo a) (k4-to-endo a')
 in (liftPerm (fst ep) ,
    trans (cong endo-to-k4 (snd ep)) (k4-endo-k4 a'))
```

2-transitivity is the key tool for the propagation elimination: for any two ordered pairs of distinct vertices, some permutation maps one to the other. The reference pair is (v_0, v_1). Each of the 12 off-diagonal targets is reached by at most two transpositions. Every case reduces by computation to refl.

```
edge-map : (v w : K4Vertex) → v ≠ w →
 Σ K4Perm (λ σ → Σ (k4to σ v₀ ≡ v) (λ _ → k4to σ v₁ ≡ w))
edge-map v₀ v₀ ne = ⊥-elim (ne refl)
edge-map v₀ v₁ _ = (liftPerm (permSwap case-constL case-constL)
                   , (refl , refl))
edge-map v₀ v₂ _ = (liftPerm (permSwap case-constR case-id)
                   , (refl , refl))
edge-map v₀ v₃ _ = (liftPerm (permSwap case-constR case-dual)
                   , (refl , refl))
edge-map v₁ v₀ _ = (liftPerm (permSwap case-constL case-constR)
                   , (refl , refl))
edge-map v₁ v₁ ne = ⊥-elim (ne refl)
edge-map v₁ v₂ _ = (k4Perm-comp (liftPerm (permSwap case-constR case-id))
                                (liftPerm (permSwap case-constL case-id))
                   , (refl , refl))
edge-map v₁ v₃ _ = (k4Perm-comp (liftPerm (permSwap case-constR case-dual))
                                (liftPerm (permSwap case-constL case-dual))
                   , (refl , refl))
edge-map v₂ v₀ _ = (k4Perm-comp (liftPerm (permSwap case-constL case-id))
                                (liftPerm (permSwap case-constR case-id))
                   , (refl , refl))
edge-map v₂ v₁ _ = (liftPerm (permSwap case-constL case-id)
                   , (refl , refl))
edge-map v₂ v₂ ne = ⊥-elim (ne refl)
edge-map v₂ v₃ _ = (k4Perm-comp (liftPerm (permSwap case-constL case-id))
                                (liftPerm (permSwap case-constR case-dual))
                   , (refl , refl))
edge-map v₃ v₀ _ = (k4Perm-comp (liftPerm (permSwap case-constL case-dual))
                                (liftPerm (permSwap case-constR case-dual))
                   , (refl , refl))
edge-map v₃ v₁ _ = (liftPerm (permSwap case-constL case-dual)
                   , (refl , refl))
edge-map v₃ v₂ _ = (k4Perm-comp (liftPerm (permSwap case-constL case-dual))
                                (liftPerm (permSwap case-constR case-id))
                   , (refl , refl))
edge-map v₃ v₃ ne = ⊥-elim (ne refl)
```

Adjacency preservation

In K_4—and only in a complete graph—every bijection is a graph automorphism. The proof does not inspect the permutation: it branches on whether the two vertices coincide. On the diagonal, both sides equal 0; off-diagonal, injectivity forces both sides to 1.

```
k4-perm-preserves-adj : (σ : K4Perm) → (v w : K4Vertex) →
 adjacent v w ≡ adjacent (k4to σ v) (k4to σ w)
k4-perm-preserves-adj σ v w with K4-decEq v w
... | inj₁ refl = trans (adj-self v) (sym (adj-self (k4to σ v)))
... | inj₂ ne = trans (K4-distinct-adj v w ne)
                      (sym (K4-distinct-adj (k4to σ v) (k4to σ w)
                            (λ p → ne (k4-injective σ v w p))))
```

K4-invariance and uniform edge weight

A numeric function on vertex pairs is K_4-invariant when its value is preserved under every permutation.

```
IsK4PermInvariant : (K4Vertex → K4Vertex → ℕ) → Set
IsK4PermInvariant f = (σ : K4Perm) → (v w : K4Vertex) →
 f v w ≡ f (k4to σ v) (k4to σ w)
```

The central consequence: any K_4-invariant function assigns the same value to every pair of distinct vertices. The proof picks two permutations—one from edge-map for each target pair—and chains the invariance equalities through the common reference value $f\, v_0\, v_1$.

```
invariant-uniform-edges : (f : K4Vertex → K4Vertex → ℕ) →
 IsK4PermInvariant f →
 (v w v' w' : K4Vertex) → v ≢ w → v' ≢ w' → f v w ≡ f v' w'
invariant-uniform-edges f inv v w v' w' ne ne' =
 trans (sym (to-ref v w ne)) (to-ref v' w' ne')
 where
  to-ref : (a b : K4Vertex) → a ≢ b → f v₀ v₁ ≡ f a b
  to-ref a b ne-ab =
   let em = edge-map a b ne-ab
       σ = fst em
       p = fst (snd em)
       q = snd (snd em)
   in trans (inv σ v₀ v₁)
            (trans (cong (λ x → f x (k4to σ v₁)) p)
                   (cong (f a) q))
```

This is the exact place where the admissibility architecture must sit. The permutation chapter supplies the transport engine: a single reference value on one edge, face, or vertex is moved across the full orbit of the same simplicial dimension. The three unit-constant chapters therefore no longer need to postulate pointwise lower and upper bounds on every simplex. It is enough to bracket one reference simplex and combine that bracket with invariance and the local diagonal law. The next three chapters apply that same pattern in dimensions 1, 2, and 0 respectively.

Chapter 47

Forced Propagation

The arithmetic identity $\text{max-propagation-per-edge} \equiv 1$ was proved earlier by reduction. That identity computes the right number but does not eliminate alternatives: it never defines what a propagation law *is*, so it never shows that rival laws fail.

This chapter closes that gap. A propagation law is any numeric function on vertex pairs, subject to four independent structural constraints—each of which admits genuine alternatives on its own. Only their intersection is a singleton. The elimination is not a case split. It is a sandwich argument: automorphism invariance collapses the off-diagonal entries to a single value r, the lower bound forces $1 \leq r$, the upper bound forces $r \leq 1$, and antisymmetry closes to $r = 1$.

Constraint: The candidate space is deliberately wide: *any* function $K_4\text{Vertex} \to K_4\text{Vertex} \to \mathbb{N}$. Candidates such as $P \equiv 2$ on all edges, or $P \equiv 3$ on one edge and 1 elsewhere, are included and must be eliminated by the filter, not excluded by the definition.

Elimination: Four filters are applied in sequence:

1. *Locality* — zero on the diagonal.

2. *Edge support* — every off-diagonal entry is at least 1.

3. K_4*-invariance* — the law is preserved under every vertex permutation.

4. *Boundedness* — every entry is at most 1.

Filters 2 and 4 are the wide brackets; filter 3 does the structural work. After invariance, the 12 off-diagonal values collapse to a single unknown $r = P\, v_0\, v_1$. Edge support gives $1 \leq r$; boundedness gives $r \leq 1$; antisymmetry of $\leq$ yields $r \equiv 1$. The diagonal is 0 by locality. Together: $P \equiv \text{adjacent}$.

Consequence: The propagation rate is forced without enumerating vertex pairs. The earlier arithmetic computation becomes a corollary of a structural elimination.

Propagation candidates

A propagation law assigns a natural-number weight to each ordered vertex pair. No constraint is placed yet—the type is deliberately wide. The constant-2 law, the constant-7 law, and every non-uniform variant are all members of this type.

```
PropagationLaw : Set
PropagationLaw = K4Vertex → K4Vertex → ℕ
```

The four admissibility filters

Locality demands zero weight on the diagonal: a vertex does not propagate to itself.

```
IsLocal : PropagationLaw → Set
IsLocal P = (v : K4Vertex) → P v v ≡ 0
```

Edge support demands that every off-diagonal pair carries weight at least 1. This is deliberately weak—it admits $P = 2$, $P = 5$, any non-zero value.

```
HasEdgeSupport : PropagationLaw → Set
HasEdgeSupport P = (v w : K4Vertex) → v ≢ w → 1 ≤ P v w

ReferenceEdgeLower : PropagationLaw → Set
ReferenceEdgeLower P = 1 ≤ P v₀ v₁
```

Boundedness demands that no single edge carries weight above 1. Structurally: propagation is local, with at most one unit of signal per direct link. No shortcutting, no amplification. This is the upper bracket that meets the lower bracket from edge support.

```
IsBounded : PropagationLaw → Set
IsBounded P = (v w : K4Vertex) → P v w ≤ 1

ReferenceEdgeUpper : PropagationLaw → Set
ReferenceEdgeUpper P = P v₀ v₁ ≤ 1
```

K_4-invariance demands that the law is preserved under every vertex permutation. This is the structural filter that, in the previous chapter, was shown to collapse all off-diagonal entries to a single value.

The full admissibility record packages all four constraints. Each constraint admits genuine alternatives on its own; only their intersection is a singleton.

```
record AdmissiblePropagation (P : PropagationLaw) : Set where
 field
  local : IsLocal P
  invariant : IsK4PermInvariant P
  ref-lower : ReferenceEdgeLower P
  ref-upper : ReferenceEdgeUpper P
```

The elimination

The elimination proceeds without enumerating vertex pairs. It uses three lemmas, each of which is structural rather than computational.

Step 1: Invariance collapses off-diagonal to one value. By invariant-uniform-edges (proved in the previous chapter), any K_4-invariant function assigns the same value r to every pair of distinct vertices. The reference value is $P\, v_0\, v_1$.

```
propagation-uniform : (P : PropagationLaw) → IsK4PermInvariant P →
 (v w : K4Vertex) → v ≠ w → P v w ≡ P v₀ v₁
propagation-uniform P inv v w ne =
 invariant-uniform-edges P inv v w v₀ v₁ ne (λ ())
```

Step 2: Invariance transports the brackets. The lower and upper brackets are imposed only on the reference edge (v_0, v_1). Invariance transports them to every off-diagonal edge.

```
propagation-supported : (P : PropagationLaw) → AdmissiblePropagation P →
 (v w : K4Vertex) → v ≠ w → 1 ≤ P v w
propagation-supported P adm v w ne =
 subst (λ n → 1 ≤ n)
  (sym (propagation-uniform P (AdmissiblePropagation.invariant adm) v w ne))
  (AdmissiblePropagation.ref-lower adm)

propagation-bounded : (P : PropagationLaw) → AdmissiblePropagation P →
 (v w : K4Vertex) → P v w ≤ 1
propagation-bounded P adm v w with K4-decEq v w
... | inj₁ refl = subst (λ n → n ≤ 1) (sym (AdmissiblePropagation.local adm v)) z≤n
... | inj₂ ne = subst (λ n → n ≤ 1)
                (sym (propagation-uniform P (AdmissiblePropagation.invariant adm) v w ne))
                (AdmissiblePropagation.ref-upper adm)
```

Step 3: The sandwich. The transported lower bound gives $1 \leq r$. The transported upper bound gives $r \leq 1$. Antisymmetry of $\leq$ closes to $r \equiv 1$.

```
v₀≠v₁ : v₀ ≠ v₁
v₀≠v₁ ()

propagation-edge-value : (P : PropagationLaw) → AdmissiblePropagation P →
 P v₀ v₁ ≡ 1
propagation-edge-value P adm =
 ≤-antisym
  (AdmissiblePropagation.ref-upper adm)
  (AdmissiblePropagation.ref-lower adm)
```

Step 4: Assembly. Every off-diagonal entry equals 1; every diagonal entry equals 0. Both agree with adjacent, whose definition is exactly 0 on the diagonal and 1 elsewhere.

```
propagation-off-diag : (P : PropagationLaw) → AdmissiblePropagation P →
 (v w : K4Vertex) → v ≠ w → P v w ≡ 1
propagation-off-diag P adm v w ne =
 trans (propagation-uniform P (AdmissiblePropagation.invariant adm) v w ne)
       (propagation-edge-value P adm)

propagation-forced : (P : PropagationLaw) → AdmissiblePropagation P →
 (v w : K4Vertex) → P v w ≡ adjacent v w
propagation-forced P adm v w with K4-decEq v w
... | inj₁ refl = trans (AdmissiblePropagation.local adm v)
                        (sym (adj-self v))
```

```
... | inj₂ ne = trans (propagation-off-diag P adm v w ne)
                     (sym (K4-distinct-adj v w ne))
```

The core theorem now branches on a single binary question—same vertex or different?—not on 16 constructor pairs. The structural work is done by invariance; the arithmetic is done by the sandwich.

Existence

The adjacency matrix itself is admissible: it satisfies all four constraints. Locality and boundedness hold by computation. Edge support follows from K4-distinct-adj. Invariance follows from k4-perm-preserves-adj.

```
adjacent-is-local : IsLocal adjacent
adjacent-is-local v₀ = refl
adjacent-is-local v₁ = refl
adjacent-is-local v₂ = refl
adjacent-is-local v₃ = refl

adjacent-supported : HasEdgeSupport adjacent
adjacent-supported v w ne = subst (λ n → 1 ≤ n)
 (sym (K4-distinct-adj v w ne)) (s≤s z≤n)

adjacent-bounded : IsBounded adjacent
adjacent-bounded v₀ v₀ = z≤n
adjacent-bounded v₀ v₁ = s≤s z≤n
adjacent-bounded v₀ v₂ = s≤s z≤n
adjacent-bounded v₀ v₃ = s≤s z≤n
adjacent-bounded v₁ v₀ = s≤s z≤n
adjacent-bounded v₁ v₁ = z≤n
adjacent-bounded v₁ v₂ = s≤s z≤n
adjacent-bounded v₁ v₃ = s≤s z≤n
adjacent-bounded v₂ v₀ = s≤s z≤n
adjacent-bounded v₂ v₁ = s≤s z≤n
adjacent-bounded v₂ v₂ = z≤n
adjacent-bounded v₂ v₃ = s≤s z≤n
adjacent-bounded v₃ v₀ = s≤s z≤n
adjacent-bounded v₃ v₁ = s≤s z≤n
adjacent-bounded v₃ v₂ = s≤s z≤n
adjacent-bounded v₃ v₃ = z≤n

adjacent-invariant : IsK4PermInvariant adjacent
adjacent-invariant σ v w = k4-perm-preserves-adj σ v w

adjacent-ref-lower : ReferenceEdgeLower adjacent
adjacent-ref-lower = s≤s z≤n

adjacent-ref-upper : ReferenceEdgeUpper adjacent
adjacent-ref-upper = s≤s z≤n

adjacent-admissible : AdmissiblePropagation adjacent
adjacent-admissible = record
 { local = adjacent-is-local
 ; invariant = adjacent-invariant
 ; ref-lower = adjacent-ref-lower
 ; ref-upper = adjacent-ref-upper
 }
```

Summary and the forced edge weight

The full result: the admissible propagation law exists, is unique, and has effective rate 1. The uniqueness is structural—invariance, sandwich, antisymmetry—not a 4×4 case table.

```
record ForcedPropagationResult : Set where
 field
  witness  : AdmissiblePropagation adjacent
  unique   : (P : PropagationLaw) → AdmissiblePropagation P →
             (v w : K4Vertex) → P v w ≡ adjacent v w
  rate-is-1 : (P : PropagationLaw) → AdmissiblePropagation P →
             (v w : K4Vertex) → adjacent v w ≡ 1 → P v w ≡ 1

theorem-forced-propagation : ForcedPropagationResult
theorem-forced-propagation = record
 { witness = adjacent-admissible
 ; unique  = propagation-forced
 ; rate-is-1 = λ P adm v w hw → trans (propagation-forced P adm v w) hw
 }
```

With the elimination closed, the propagation rate can be named for what it is: the unit propagation weight in native FD units. The value *edge-weight* $= 1$ is not a numerical input or a convenient convention. It is the only value that survives the four-filter admissibility test.

```
edge-weight : ℕ
edge-weight = 1

edge-weight-is-propagation-rate : edge-weight ≡ max-propagation-per-edge
edge-weight-is-propagation-rate = refl
```

Chapter 48

Forced Minimal Action

K_4 has a forced cycle structure. At the tetrahedral level there are exactly four triangular faces, one opposite each vertex, and these are the minimal non-trivial closed simplicial loops of the graph. An action law assigns a natural-number weight to each face. The elimination now uses the same symmetry logic as the propagation chapter: automorphism-invariance under $\mathrm{Aut}(K_4)$ collapses all four faces to one global value, and minimality pins that value at 1.

Constraint: The candidate space must not encode the target value. An action law is any function from triangles to $\mathbb{N}$, and the constraints are external filters.

Elimination: Four filters are applied:

1. *Non-triviality* — every face has positive weight.
2. K_4*-invariance* — the law is preserved under every vertex permutation.
3. *Lower bound* — every face carries weight at least 1.
4. *Minimality* — no face carries weight above 1.

Filters 3 and 4 are the wide brackets; filter 2 does the structural work. After invariance, the four face values collapse to a single unknown $r = A\,tri\text{-}012$. The lower bound gives $1 \leq r$; minimality gives $r \leq 1$; antisymmetry of $\leq$ yields $r \equiv 1$.

Consequence: The forced face weight *face-weight* $= 1$ is forced by a sandwich argument parallel to propagation. The earlier arithmetic statement $\mathrm{triangle\text{-}loop\text{-}order} = 1$ becomes a corollary.

Triangles and action candidates

A triangle face of the tetrahedral K_4 is determined by the unique vertex it omits. There are therefore exactly four such faces, one opposite each vertex. This representation is the right one for automorphism-invariance: a vertex permutation acts on faces simply by acting on the omitted vertex.

```
K4Triangle : Set
K4Triangle = K4Vertex
```

```
triangle-map : K4Perm → K4Triangle → K4Triangle
triangle-map σ t = k4to σ t
```

An action law assigns a natural-number weight to each triangle. No constraint is assumed yet.

```
ActionLaw : Set
ActionLaw = K4Triangle → ℕ

tri-012 : K4Triangle
tri-012 = v₃

tri-013 : K4Triangle
tri-013 = v₂

tri-023 : K4Triangle
tri-023 = v₁

tri-123 : K4Triangle
tri-123 = v₀
```

The four admissibility conditions mirror the propagation chapter: non-triviality, automorphism-invariance, a lower bound, and a minimality upper bound. Each filter admits genuine alternatives on its own; only their intersection is a singleton.

```
IsNonTrivial : ActionLaw → Set
IsNonTrivial A = (t : K4Triangle) → A t ≡ 0 → ⊥

IsActionInvariant : ActionLaw → Set
IsActionInvariant A = (σ : K4Perm) → (t : K4Triangle) →
 A t ≡ A (triangle-map σ t)

ActionBound : ActionLaw → Set
ActionBound A = (t : K4Triangle) → 1 ≤ A t

ReferenceTriangleLower : ActionLaw → Set
ReferenceTriangleLower A = 1 ≤ A tri-012

IsMinimal : ActionLaw → Set
IsMinimal A = (t : K4Triangle) → A t ≤ 1

ReferenceTriangleUpper : ActionLaw → Set
ReferenceTriangleUpper A = A tri-012 ≤ 1

record AdmissibleAction (A : ActionLaw) : Set where
 field
  invariant : IsActionInvariant A
  ref-lower : ReferenceTriangleLower A
  ref-upper : ReferenceTriangleUpper A
```

The four canonical triangle faces of K_4 are the faces opposite v_3, v_2, v_1, and v_0 respectively.

Existence: the unit action law

The constant-1 action law is admissible: it is trivially invariant, its value is never zero, every triangle satisfies $1 \leq 1$, and no triangle exceeds 1.

```
unit-action : ActionLaw
unit-action _ = 1

unit-action-invariant : IsActionInvariant unit-action
unit-action-invariant _ _ = refl

unit-action-bounded : ActionBound unit-action
unit-action-bounded _ = s≤s z≤n

unit-action-minimal : IsMinimal unit-action
unit-action-minimal _ = s≤s z≤n

unit-action-ref-lower : ReferenceTriangleLower unit-action
unit-action-ref-lower = s≤s z≤n

unit-action-ref-upper : ReferenceTriangleUpper unit-action
unit-action-ref-upper = s≤s z≤n

unit-action-admissible : AdmissibleAction unit-action
unit-action-admissible = record
 { invariant = unit-action-invariant
 ; ref-lower = unit-action-ref-lower
 ; ref-upper = unit-action-ref-upper
 }
```

Construction: invariance and the sandwich pin a single value

Automorphism-invariance forces every admissible action law to a single global value: all four faces lie in one orbit, and the sandwich $1 \leq A(t) \leq 1$ pins the value by antisymmetry.

```
action-from-012 : (A : ActionLaw) → AdmissibleAction A →
 (t : K4Triangle) → A tri-012 ≡ A t
action-from-012 A adm t =
 let st = k4Perm-send tri-012 t in
 let σ = fst st in
 let p = snd st in
 trans (AdmissibleAction.invariant adm σ tri-012)
       (cong A p)

action-all-equal-to-012 : (A : ActionLaw) → AdmissibleAction A →
 (t : K4Triangle) → A t ≡ A tri-012
action-all-equal-to-012 A adm t =
 sym (action-from-012 A adm t)

action-global-value : (A : ActionLaw) → AdmissibleAction A →
 (t₁ t₂ : K4Triangle) → A t₁ ≡ A t₂
action-global-value A adm t₁ t₂ =
 trans (action-all-equal-to-012 A adm t₁)
       (action-from-012 A adm t₂)
```

Invariance transports the brackets. The lower and upper brackets are imposed only on the reference face *tri*-012. Invariance transports them to every triangle.

```
action-bound : (A : ActionLaw) → AdmissibleAction A → ActionBound A
action-bound A adm t =
 subst (λ n → 1 ≤ n)
  (action-from-012 A adm t)
  (AdmissibleAction.ref-lower adm)

action-minimal : (A : ActionLaw) → AdmissibleAction A → IsMinimal A
action-minimal A adm t =
 subst (λ n → n ≤ 1)
  (action-from-012 A adm t)
  (AdmissibleAction.ref-upper adm)

action-nontrivial : (A : ActionLaw) → AdmissibleAction A → IsNonTrivial A
action-nontrivial A adm t eq =
 suc≤-impossible zero (subst (λ n → 1 ≤ n) eq (action-bound A adm t))
```

The sandwich. The lower bound gives $1 \leq A$ *tri*-012. The upper bound gives A *tri*-012 ≤ 1. Antisymmetry closes to A *tri*-012 $\equiv 1$.

```
action-ref-value : (A : ActionLaw) → AdmissibleAction A → A tri-012 ≡ 1
action-ref-value A adm =
 ≤-antisym (AdmissibleAction.ref-upper adm)
           (AdmissibleAction.ref-lower adm)
```

Assembly. Every face equals 1: invariance collapses to the reference value, the sandwich pins that value.

```
action-forced : (A : ActionLaw) → AdmissibleAction A →
 (t : K4Triangle) → A t ≡ 1
action-forced A adm t =
 trans (action-all-equal-to-012 A adm t)
       (action-ref-value A adm)
```

The core theorem branches on no cases at all. The structural work is done by invariance; the arithmetic is done by the sandwich—exactly as in the propagation chapter.

The summary record packages existence, unconditional uniqueness, and the global value.

```
record ForcedActionResult : Set where
 field
  witness  : AdmissibleAction unit-action
  global-value : (A : ActionLaw) → AdmissibleAction A →
                 (t₁ t₂ : K4Triangle) → A t₁ ≡ A t₂
  unique   : (A : ActionLaw) → AdmissibleAction A →
                 (t : K4Triangle) → A t ≡ 1

theorem-forced-action : ForcedActionResult
theorem-forced-action = record
 { witness = unit-action-admissible
 ; global-value = action-global-value
 ; unique  = action-forced
 }
```

The forced face weight

The forced face weight *face-weight* $= 1$ names the unique admissible action value in native FD units. The value is not merely minimal—it is the only survivor of the four-filter elimination. It is consistent with the triangle loop order already computed.

```
face-weight : ℕ
face-weight = 1

face-weight-is-loop-order : face-weight ≡ triangle-loop-order

Chapter 49

Forced Vertex Weight

The three forced constants of the FD system live on three simplicial dimensions of K_4:

$$\begin{array}{lll} \text{dim } 1 & \text{(edges)} & \longrightarrow \textit{ edge-weight} \\ \text{dim } 2 & \text{(faces)} & \longrightarrow \textit{ face-weight} \\ \text{dim } 0 & \text{(vertices)} & \longrightarrow \textit{ vertex-weight} \end{array}$$

Propagation assigns a weight to each edge; the action assigns a weight to each face. Both were eliminated by the same four-filter sandwich. The vertex weight completes the triple: it assigns a curvature weight to each *vertex*—the 0-simplices where, in discrete geometry, curvature concentrates.

A curvature law is any function $K_4\text{Vertex} \to \mathbb{N}$, subject to four constraints—each of which admits genuine alternatives on its own:

1. *Non-triviality* — every vertex carries positive curvature.

2. K_4*-invariance* — the law is preserved under every vertex permutation.

3. *Lower bound* — every vertex carries curvature at least 1.

4. *Minimality* — no vertex carries curvature above 1.

The sandwich argument is identical to propagation and action: invariance collapses all four vertex values to a single unknown r, the lower bound gives $1 \leq r$, minimality gives $r \leq 1$, antisymmetry of $\leq$ yields $r \equiv 1$.

Constraint: The candidate space is deliberately wide: *any* function $K_4\text{Vertex} \to \mathbb{N}$. The constant-2 law, the constant-5 law, and any non-uniform variant are all members. The filters are external.

Elimination: Four filters applied in sequence collapse the space to a singleton.

Consequence: The forced vertex weight *vertex-weight* $= 1$ is forced by the same simplicial elimination that forces the edge and face weights. All three constants arise from the same architecture applied to three simplicial dimensions.

Curvature candidates

A curvature law assigns a natural-number weight to each vertex of K_4. No constraint is placed yet—the type is deliberately wide.

```
CurvatureLaw : Set
CurvatureLaw = K4Vertex → ℕ
```

The four admissibility conditions mirror the propagation and action chapters exactly.

```
IsCurvatureNonTrivial : CurvatureLaw → Set
IsCurvatureNonTrivial C = (v : K4Vertex) → C v ≡ 0 → ⊥

IsCurvatureInvariant : CurvatureLaw → Set
IsCurvatureInvariant C = (σ : K4Perm) → (v : K4Vertex) →
 C v ≡ C (k4to σ v)

CurvatureBound : CurvatureLaw → Set
CurvatureBound C = (v : K4Vertex) → 1 ≤ C v

ReferenceVertexLower : CurvatureLaw → Set
ReferenceVertexLower C = 1 ≤ C v₀

IsCurvatureMinimal : CurvatureLaw → Set
IsCurvatureMinimal C = (v : K4Vertex) → C v ≤ 1

ReferenceVertexUpper : CurvatureLaw → Set
ReferenceVertexUpper C = C v₀ ≤ 1

record AdmissibleCurvature (C : CurvatureLaw) : Set where
 field
  invariant : IsCurvatureInvariant C
  ref-lower : ReferenceVertexLower C
  ref-upper : ReferenceVertexUpper C
```

Existence: the unit curvature law

The constant-1 curvature law is admissible: it is trivially invariant, its value is never zero, every vertex satisfies $1 \leq 1$, and no vertex exceeds 1.

```
unit-curvature : CurvatureLaw
unit-curvature _ = 1

unit-curvature-invariant : IsCurvatureInvariant unit-curvature
unit-curvature-invariant _ _ = refl

unit-curvature-bounded : CurvatureBound unit-curvature
unit-curvature-bounded _ = s≤s z≤n

unit-curvature-minimal : IsCurvatureMinimal unit-curvature
unit-curvature-minimal _ = s≤s z≤n

unit-curvature-ref-lower : ReferenceVertexLower unit-curvature
unit-curvature-ref-lower = s≤s z≤n

unit-curvature-ref-upper : ReferenceVertexUpper unit-curvature
unit-curvature-ref-upper = s≤s z≤n

unit-curvature-admissible : AdmissibleCurvature unit-curvature
unit-curvature-admissible = record
 { invariant = unit-curvature-invariant
 ; ref-lower = unit-curvature-ref-lower
 ; ref-upper = unit-curvature-ref-upper
 }
```

Construction: invariance and the sandwich pin a single value

Automorphism-invariance forces every admissible curvature law to a single global value: all four vertices lie in one orbit under $\mathrm{Aut}(K_4)$, and the sandwich $1 \leq C(v) \leq 1$ pins the value by antisymmetry.

```
curvature-from-v0 : (C : CurvatureLaw) → AdmissibleCurvature C →
 (v : K4Vertex) → C v₀ ≡ C v
curvature-from-v0 C adm v =
 let st = k4Perm-send v₀ v in
 let σ = fst st in
 let p = snd st in
 trans (AdmissibleCurvature.invariant adm σ v₀)
       (cong C p)

curvature-all-equal-to-v0 : (C : CurvatureLaw) → AdmissibleCurvature C →
 (v : K4Vertex) → C v ≡ C v₀
curvature-all-equal-to-v0 C adm v =
 sym (curvature-from-v0 C adm v)

curvature-global-value : (C : CurvatureLaw) → AdmissibleCurvature C →
 (v₁ v₂ : K4Vertex) → C v₁ ≡ C v₂
curvature-global-value C adm u w =
 trans (curvature-all-equal-to-v0 C adm u)
       (curvature-from-v0 C adm w)
```

Invariance transports the brackets. The lower and upper brackets are imposed only on the reference vertex v_0. Invariance transports them to every vertex.

```
curvature-bound : (C : CurvatureLaw) → AdmissibleCurvature C → CurvatureBound C
curvature-bound C adm v =
 subst (λ n → 1 ≤ n)
  (curvature-from-v0 C adm v)
  (AdmissibleCurvature.ref-lower adm)

curvature-minimal : (C : CurvatureLaw) → AdmissibleCurvature C → IsCurvatureMinimal C
curvature-minimal C adm v =
 subst (λ n → n ≤ 1)
  (curvature-from-v0 C adm v)
  (AdmissibleCurvature.ref-upper adm)

curvature-nontrivial : (C : CurvatureLaw) → AdmissibleCurvature C → IsCurvatureNonTrivial C
curvature-nontrivial C adm v eq =
 suc≤-impossible zero (subst (λ n → 1 ≤ n) eq (curvature-bound C adm v))
```

The sandwich. The lower bound gives $1 \leq C\,v_0$. The upper bound gives $C\,v_0 \leq 1$. Antisymmetry closes to $C\,v_0 \equiv 1$.

```
curvature-ref-value : (C : CurvatureLaw) → AdmissibleCurvature C → C v₀ ≡ 1
curvature-ref-value C adm =
 ≤-antisym (AdmissibleCurvature.ref-upper adm)
           (AdmissibleCurvature.ref-lower adm)
```

Assembly. Every vertex equals 1: invariance collapses to the reference value, the sandwich pins that value.

```
curvature-forced : (C : CurvatureLaw) → AdmissibleCurvature C →
 (v : K4Vertex) → C v ≡ 1
curvature-forced C adm v =
 trans (curvature-all-equal-to-v0 C adm v)
       (curvature-ref-value C adm)
```

The forced vertex weight

The summary record packages existence, unconditional uniqueness, and the global value—exactly parallel to the propagation and action results.

```

```

Filter audit: sufficiency versus minimality

The three preceding chapters force their target constants by orbit-transport plus sandwich. A sharper question follows: are the four filters in each chapter themselves already minimal, or do some of them follow from the others? The answer matters, because a redundant filter is still a correct hypothesis, but it is not yet an irreducible one. The eliminative work that answers it lives in the audit lemmata below.

The constant chapters do not impose pointwise lower and upper brackets on every simplex. Instead they impose those brackets only on a distinguished reference simplex and use automorphism-invariance to transport them across the full orbit. This makes invariance genuinely structural.

The audit lemmas below justify that architecture. They show that a pointwise form—brackets imposed on every simplex independently—would be too strong: the four filters would no longer

be independent, and some would follow from others. The reference-simplex form avoids that collapse.

```

curvature-forced-no-invariance C lower upper v =
 ≤-antisym (upper v) (lower v)
```

The force of these lemmas is conceptual, not destructive. They do *not* weaken the uniqueness theorems; they justify the choice of admissibility basis. The constant chapters prove uniqueness with a genuinely non-pointwise admissibility architecture, and these lemmas confirm that the pointwise alternative would have been redundant. The question of whether an alternative set of predicates could achieve the same singleton collapse belongs to the meta-theory of filter selection rather than to the elimination itself.

Minimal admissibility basis

The admissibility architecture has four primitive clauses in the propagation chapter and three primitive clauses in the action and curvature chapters. To justify calling this basis *minimal*, each primitive clause must now be shown indispensable: if it is removed while the others are kept, a rival law survives.

The proofs are by concrete witness. Each witness satisfies all remaining primitive clauses but fails the target conclusion. This is the right notion of necessity here: not rhetorical indispensability, but a formal countermodel to omission.

Propagation basis. Without locality, the everywhere-one law survives. Without invariance, a law can single out the reference edge and ignore the rest. Without the lower bracket, the zero law survives. Without the upper bracket, the doubled adjacency law survives.

```

These witnesses prove that the admissibility basis is irreducible: every primitive clause excludes a live rival that the remaining clauses cannot block. Removing any single clause breaks the singleton collapse. Nothing remaining in the basis is decorative.

Filter minimality: invariance is non-redundant. A sharper question: is the K_4-invariance filter genuinely eliminative, or do the other three filters (locality/non-triviality, lower bound, upper bound) already force the unit constant? The answer is no—without invariance, a rival candidate survives in each simplicial dimension.

For propagation, the reference-only law $P(v_0, v_1) = 1$, $P = 0$ elsewhere, satisfies locality, the lower bracket on the reference edge, and the upper bracket—but is not K_4-invariant. Invariance is therefore the filter that blocks this candidate. For the action and curvature, the same pattern repeats: the reference-only face law and the reference-only vertex law satisfy every filter except invariance.

Constraint: Each forced-constant theorem uses four filters. Minimality requires that no proper subset suffices.

Elimination: For each simplicial dimension, a concrete rival is exhibited that passes every filter except K_4-invariance. The rival is local (or non-trivial), satisfies both bounds, but fails uniformity across the orbit. The invariance filter annihilates it.

Consequence: The invariance filter is non-redundant in all three simplicial dimensions. The four-filter architecture is minimal: removing any one filter breaks the singleton collapse.

```

 curvature-reference-only-not-forced)
```

Invariance blocks the reference-only rival in all three simplicial dimensions. The same argument structure extends to the remaining filters: in each case, a concrete counterexample passes all filters but one, proving that filter essential. The derivation closes when every filter is traced to a graph-theoretic property of K_4.

Filter derivation: the lower bound is non-redundant. The zero law assigns weight 0 to every simplex. It satisfies locality (propagation: $P(v, v) = 0$ trivially), K_4-invariance (trivially), and the upper bracket ($0 \leq 1$). It fails the lower bracket: $1 \leq 0$ is false. Without the lower bound, the zero law survives in every simplicial dimension.

The lower bound is not a design choice. K_4 is the complete graph on four vertices: every possible edge, face, and vertex exists. A weight of 0 on an existing simplex declares it structurally absent—it carries no content, contributes nothing to the simplicial complex. This contradicts completeness. Non-degeneracy (≥ 1 on the reference simplex) is forced by the fact that K_4 has no missing simplices.

Filter derivation: the upper bound is non-redundant. The doubled law (propagation: $P(v, w) = 2 \cdot \text{adjacent}(v, w)$) and the constant-2 law (action, curvature) are invariant and non-degenerate. They satisfy locality (propagation) and the lower bracket. They fail the upper bracket: $2 \leq 1$ is false. Without the upper bound, these rivals survive.

The upper bound is forced by the zero-parameter constraint. In $\mathbb{N}$, once non-degeneracy fixes a lower bound of 1, any value $n > 1$ requires an external input distinguishing it from 1. That input would be a free parameter. Since the system admits none, the weight collapses to the

minimal non-degenerate value. Minimality (≤ 1 on the reference simplex) is the arithmetical shadow of having zero free parameters.

Filter derivation: locality is non-redundant (propagation). The constant-1 law assigns weight 1 to every vertex pair, including the diagonal. It is K_4-invariant, non-degenerate, and minimal. It fails locality: $P(v, v) = 1 \neq 0$. Without locality, this rival survives in the propagation dimension.

Locality is forced by K_4 being a simple graph. A simple graph has no self-loops: there is no edge from a vertex to itself. The propagation kernel must vanish on the diagonal because there is no simplex to propagate along. This constraint has no analogue in the action and curvature dimensions, where every simplex is a distinct combinatorial object.

The derivation theorem. Four structural properties of K_4—transitivity of $\mathrm{Aut}(K_4)$ on each simplicial orbit, completeness, simplicity, and the absence of free parameters—generate exactly the admissibility filters used in the three forced-constant chapters. Each property produces one filter:

K_4 **property**	**Filter**	**Derived from**
$\mathrm{Aut}(K_4)$ transitivity	invariance	labeling independence
completeness (no missing simplices)	lower bound ≥ 1	non-degeneracy
zero free parameters	upper bound ≤ 1	minimality
simplicity (no self-loops)	locality ($P(v, v) = 0$)	propagation only

Completeness is proved by the three forced-constant theorems (each filter set forces a unique unit weight). Irredundancy is proved by ten essentiality witnesses: four for propagation, three each for action and curvature. Every proper subset of filters admits a concrete rival that the remaining filters cannot block.

Constraint: The set of admissibility filters is not postulated; it must be derivable from the graph-theoretic structure of K_4, or it introduces a hidden assumption.

Elimination: For each filter, a concrete rival is exhibited that passes all remaining filters but fails the one in question. Ten such witnesses—one per filter per simplicial dimension—prove that no filter is redundant. Simultaneously, the three forced-constant theorems prove that no filter is missing: with all filters active, a unique unit weight survives.

Consequence: The admissibility basis is the unique minimal complete filter set on the K_4 simplicial complex. It is derived from four graph-theoretic properties of K_4. The filter architecture is closed.

```

The filter architecture is closed. Ten essentiality witnesses prove irredundancy; three forced-constant theorems prove completeness. The admissibility basis is the unique minimal complete filter set on the K_4 simplicial complex, derived from the graph-theoretic identity of K_4 as a complete, simple, vertex-transitive graph with no free parameters.

Chapter 50

Forced Edge and Matching Orbits

The vertex-permutation chapter delivered a single bahn on K_4Vertex: any vertex is sent to any other, and any K_4-invariant function on vertex pairs collapses to one off-diagonal value. That collapse acts on *ordered* pairs. But the adjacency relation in K_4 is symmetric—*adjacent* $v\,w \equiv$ *adjacent* $w\,v$ holds by computation—so any model that distinguishes (v, w) from (w, v) as edges contradicts what the graph reports. The orientation degree of freedom on each pair is annihilated by the swap-symmetry of the underlying relation. What remains is the unordered pair: the edge.

The same elimination cascades. Once edges are forced into ungeordnete Paare, an action of K_4Perm on edges is determined: it transports both endpoints simultaneously, and any candidate that fails to commute with the endpoint swap is killed by the symmetry of adjacent. Once that action is fixed, the orbit count is forced too: any pair of distinct edges that lay in different orbits would supply a witness against invariant-uniform-edges, contradicting the propagation collapse already proved. Six edges, one orbit.

The next dimension closes by the same logic. The 4 vertices of the tetrahedron permit exactly 3 partitions into two disjoint vertex-pairs—no more, since each partition is forced once the partner of v_0 is chosen, and the three choices $\{v_1, v_2, v_3\}$ exhaust the alternatives. These are the perfect matchings $\{01, 23\}$, $\{02, 13\}$, $\{03, 12\}$. Any candidate "matching" that contains overlapping edges is annihilated by the disjointness filter; any candidate that omits a vertex is annihilated by the totality filter. Only three structures survive. The transpositions $(1\,2)$, $(1\,3)$, $(2\,3)$ then send each of the three matchings into each other, so the three survivors form a single Aut(K_4)-orbit.

Constraint: Edges of K_4 are unordered pairs of distinct vertices, and perfect matchings are partitions of the four vertices into two disjoint pairs. Both structures must be enumerable, exhausted, and connected under Aut(K_4); otherwise the orbit counts depend on a choice and the symmetry of adjacent is not inherited.

Elimination and Construction: The chapter delivers five genuine eliminations. edge-classify eliminates every edge candidate not _≈E_-equivalent to one of the six named edges, by absurdity on the diagonal patterns and swap-orient on the swapped patterns. edge-act-unique eliminates every edge action that fails to coincide with pointwise transport: any candidate satisfying the lift predicate collapses to edge-act up to _≈E_, and any candidate failing

the predicate is excluded by definition. edge-transitive eliminates every conjectured second edge orbit by exhibiting the connecting K4Perm. matching-classify eliminates every fourth matching candidate by absurdity on the partner-of-v_0 datum. matching-transitive eliminates every conjectured second matching orbit by exhibiting nine connecting permutations. The constructions K4Edge, _≈E_, edge-act, K4Matching, and the three named transpositions name the structures that survive.

Consequence: Three orbit counts survive: vertex orbit count $= 1$, edge orbit count $= 1$, matching orbit count $= 1$. The edge enumeration $|K_4\text{Edge}/_\approx\text{E}_| = 6$ and the matching enumeration $|K_4\text{Matching}| = 3$ are forced by exhaustive case analysis on K4Vertex, not by stipulation. Any later law that asserts a distinction between two edges or between two perfect matchings is reduced to absurdity by the corresponding transport theorem.

Edges as unordered pairs

A K_4 edge is built from two distinct vertices. Any record that omitted the distinctness witness would admit the diagonal as an edge—contradicting adj-self, which forces *adjacent* $v\,v \equiv 0$. The distinctness field is therefore not optional decoration; it is the residue of the elimination that excludes diagonals from the edge type.

Constraint: The edge type must reject diagonal pairs (forced by adj-self) and treat orientation-swapped pairs as the same edge (forced by the symmetry of adjacent).

Construction: The record K4Edge packages two vertices and a distinctness witness, the relation _≈E_ closes under same-orient and swap-orient, and swap-edge swaps the two endpoints. Reflexivity ≈E-refl and the involution lemma swap-edge-involutive both close by refl once the records are unfolded.

Consequence: swap-edge is its own involution up to _≈E_. The exhaustion claim "every K4Edge is one of six up to _≈E_" is discharged below by edge-classify.

```
record K4Edge : Set where
 constructor edge
 field
  src  : K4Vertex
  dst  : K4Vertex
  distinct : src ≠ dst

open K4Edge public

swap-edge : K4Edge → K4Edge
swap-edge e = record
 { src = dst e
 ; dst = src e
 ; distinct = λ p → distinct e (sym p)
 }

data _≈E_ : K4Edge → K4Edge → Set where
 same-orient : (e₁ e₂ : K4Edge) →
               src e₁ ≡ src e₂ → dst e₁ ≡ dst e₂ → e₁ ≈E e₂
 swap-orient : (e₁ e₂ : K4Edge) →
               src e₁ ≡ dst e₂ → dst e₁ ≡ src e₂ → e₁ ≈E e₂
```

```
≈E-refl : (e : K4Edge) → e ≈E e
≈E-refl e = same-orient e e refl refl

swap-edge-≈E : (e : K4Edge) → swap-edge e ≈E e
swap-edge-≈E e = swap-orient (swap-edge e) e refl refl

swap-edge-involutive : (e : K4Edge) → swap-edge (swap-edge e) ≈E e
swap-edge-involutive e = same-orient (swap-edge (swap-edge e)) e refl refl
```

The six concrete edges of K_4—all $\binom{4}{2}$ unordered pairs of vertices—are named once for use in the matching classification.

```
e01 e02 e03 e12 e13 e23 : K4Edge
e01 = edge v₀ v₁ (λ ())
e02 = edge v₀ v₂ (λ ())
e03 = edge v₀ v₃ (λ ())
e12 = edge v₁ v₂ (λ ())
e13 = edge v₁ v₃ (λ ())
e23 = edge v₂ v₃ (λ ())
```

The six named edges are not a convenient list; they are the complete enumeration. Every K4Edge is ≈E-equivalent to exactly one of them, and the three diagonal cases (v_i, v_i) are absurd via the distinctness witness. The classification splits sixteen ordered-pair patterns into twelve survivors, paired by swap-orient into the six unordered classes.

Constraint: The edge type admits at most $4 \times 4 = 16$ ordered-pair shapes; four are killed by distinct and the remaining twelve must collapse pairwise under _≈E_ to deliver a finite, exhaustive enumeration.

Elimination: The four diagonal patterns (v_i, v_i) are annihilated by distinct refl. The twelve off-diagonal patterns are partitioned into six _≈E_-classes by same-orient on six of them and swap-orient on the swapped six. No seventh class can survive.

Consequence: The six concrete edges $e_{01}, e_{02}, e_{03}, e_{12}, e_{13}, e_{23}$ exhaust K4Edge/_≈E_.

```
edge-classify : (e : K4Edge) →
                (e ≈E e01) ⊎ (e ≈E e02) ⊎ (e ≈E e03) ⊎
                (e ≈E e12) ⊎ (e ≈E e13) ⊎ (e ≈E e23)
edge-classify (edge v₀ v₀ d) = ⊥-elim (d refl)
edge-classify (edge v₀ v₁ d) = inj₁ (same-orient _ _ refl refl)
edge-classify (edge v₀ v₂ d) = inj₂ (inj₁ (same-orient _ _ refl refl))
edge-classify (edge v₀ v₃ d) = inj₂ (inj₂ (inj₁ (same-orient _ _ refl refl)))
edge-classify (edge v₁ v₀ d) = inj₁ (swap-orient _ _ refl refl)
edge-classify (edge v₁ v₁ d) = ⊥-elim (d refl)
edge-classify (edge v₁ v₂ d) = inj₂ (inj₂ (inj₂ (inj₁ (same-orient _ _ refl refl))))
edge-classify (edge v₁ v₃ d) = inj₂ (inj₂ (inj₂ (inj₂ (inj₁ (same-orient _ _ refl refl)))))
edge-classify (edge v₂ v₀ d) = inj₂ (inj₁ (swap-orient _ _ refl refl))
edge-classify (edge v₂ v₁ d) = inj₂ (inj₂ (inj₂ (inj₁ (swap-orient _ _ refl refl))))
edge-classify (edge v₂ v₂ d) = ⊥-elim (d refl)
edge-classify (edge v₂ v₃ d) = inj₂ (inj₂ (inj₂ (inj₂ (inj₂ (same-orient _ _ refl refl)))))
edge-classify (edge v₃ v₀ d) = inj₂ (inj₂ (inj₁ (swap-orient _ _ refl refl)))
edge-classify (edge v₃ v₁ d) = inj₂ (inj₂ (inj₂ (inj₂ (inj₁ (swap-orient _ _ refl refl)))))
edge-classify (edge v₃ v₂ d) = inj₂ (inj₂ (inj₂ (inj₂ (inj₂ (swap-orient _ _ refl refl)))))
edge-classify (edge v₃ v₃ d) = ⊥-elim (d refl)
```

The induced edge action

A K_4Perm permutes the four vertices. Its canonical action on an edge transports both endpoints simultaneously; the result inherits its distinctness witness from the injectivity of the underlying permutation. The lemma edge-act-swap certifies that this action commutes with swap-edge up to _≈E_. A separate uniqueness theorem then shows that *any* action that transports endpoints—in either orientation—is forced to coincide with edge-act up to _≈E_; every other behaviour is annihilated.

Constraint: An action of K_4Perm on K_4Edge must (i) preserve the edge type, including the distinctness witness, and (ii) transport endpoints to the σ-image of the input endpoints—otherwise it fabricates vertices outside $\{\sigma \cdot \mathit{src}\, e,\ \sigma \cdot \mathit{dst}\, e\}$ or breaks the swap-symmetry of adjacent.

Elimination: The pointwise transport satisfies (i) by carrying the input distinctness through k4-injective, and satisfies (ii) by definition. Any rival action that fails the lift predicate LiftsEdgeAction is excluded by definition; any rival that satisfies it is annihilated by edge-act-unique, which closes both orientation cases by direct case analysis.

Consequence: edge-act is the unique edge action up to _≈E_. It commutes with swap-edge on the nose, and the identity permutation acts trivially.

```
edge-act : K4Perm → K4Edge → K4Edge
edge-act σ e = record
 { src = k4to σ (src e)
 ; dst = k4to σ (dst e)
 ; distinct = λ p → distinct e (k4-injective σ (src e) (dst e) p)
 }

edge-act-swap : (σ : K4Perm) → (e : K4Edge) →
                edge-act σ (swap-edge e) ≈E swap-edge (edge-act σ e)
edge-act-swap σ e = same-orient _ _ refl refl
```

The identity K4Perm acts trivially on every edge—a sanity check that the action is correctly normalised.

```
id-perm : K4Perm
id-perm = record
 { k4to   = λ v → v
 ; k4from = λ v → v
 ; k4-to-from = λ _ → refl
 ; k4-from-to = λ _ → refl
 }

edge-act-id : (e : K4Edge) → edge-act id-perm e ≈E e
edge-act-id e = same-orient _ _ refl refl
```

The action is unique. Any function $\mathit{act} : K_4\mathrm{Perm} \to K_4\mathrm{Edge} \to K_4\mathrm{Edge}$ whose result has endpoints drawn from $\{\sigma \cdot \mathit{src}\, e,\ \sigma \cdot \mathit{dst}\, e\}$ as a multiset—that is, every action that liftet σ to edges by acting on endpoints in some orientation—is forced to coincide with edge-act up to _≈E_. Any rival that produces an endpoint outside this multiset fails the lift predicate by definition and is excluded; any rival that satisfies the predicate is annihilated by direct case analysis on the orientation tag.

Constraint: An action of K_4Perm on K_4Edge that does not transport endpoints to the σ-image of the input endpoints would either fabricate vertices not in $\{\sigma{\cdot}\mathit{src}\, e,\ \sigma{\cdot}\mathit{dst}\, e\}$ or break the swap-symmetry of adjacent. The lift predicate LiftsEdgeAction captures exactly the admissible candidates.

Elimination: Any candidate that fails LiftsEdgeAction is excluded by the predicate itself. Any candidate that satisfies it falls into one of two cases by the orientation tag; same-orient closes the first case, swap-orient closes the second. No third behaviour survives.

Consequence: Pointwise transport is the unique edge action up to _≈E_. The lemma edge-act-unique discharges every conjectural rival.

```
LiftsEdgeAction : (K4Perm → K4Edge → K4Edge) → Set
LiftsEdgeAction act = (σ : K4Perm) → (e : K4Edge) →
 ((src (act σ e) ≡ k4to σ (src e)) × (dst (act σ e) ≡ k4to σ (dst e)))
 ⊎
 ((src (act σ e) ≡ k4to σ (dst e)) × (dst (act σ e) ≡ k4to σ (src e)))

edge-act-lifts : LiftsEdgeAction edge-act
edge-act-lifts σ e = inj₁ (refl , refl)

edge-act-unique : (act : K4Perm → K4Edge → K4Edge) →
                  LiftsEdgeAction act →
                  (σ : K4Perm) → (e : K4Edge) →
                  act σ e ≈E edge-act σ e
edge-act-unique act lifts σ e with lifts σ e
... | inj₁ (ps , pd) = same-orient _ _ ps pd
... | inj₂ (ps , pd) = swap-orient _ _ ps pd
```

The inverse of a K4Perm is forced: the only data are forward and backward maps with mutual round-trips, so swapping the roles produces another valid permutation, which the round-trip witnesses certify.

```
k4Perm-inv : K4Perm → K4Perm
k4Perm-inv σ = record
 { k4to     = k4from σ
 ; k4from = k4to σ
 ; k4-to-from = k4-from-to σ
 ; k4-from-to = k4-to-from σ
 }
```

Single edge orbit

The propagation chapter already destroyed the possibility of two distinct K_4-invariant values on off-diagonal vertex pairs. Lifting that result to edges requires only one composition: the canonical sender supplied by edge-map maps (v_0, v_1) to any chosen pair of distinct vertices, and inverting one such sender and composing with another moves any edge to any other. There is no edge that escapes this orbit; therefore there is exactly one.

Constraint: A second edge orbit would supply two distinct off-diagonal pairs (a, b) and (c, d) that no K4Perm connects. Any K_4-invariant function would then be free to assign different values to the two orbits, contradicting invariant-uniform-edges.

Construction: The composition $\sigma_2 \circ \sigma_1^{-1}$ — where σ_1 sends (v_0, v_1) to the source edge endpoints and σ_2 sends (v_0, v_1) to the target edge endpoints — is forged by k4Perm-comp and the inversion law of k4Perm-send. The Σ-witness records both the permutation and its endpoint action up to _≈E_; no auxiliary lemma intervenes.

Consequence: The orbit count on K4Edge under edge-act is exactly 1.

```
edge-transitive : (e₁ e₂ : K4Edge) →
                  Σ K4Perm (λ σ → edge-act σ e₁ ≈E e₂)
edge-transitive e₁ e₂ =
 let em₁ = edge-map (src e₁) (dst e₁) (distinct e₁)
     em₂ = edge-map (src e₂) (dst e₂) (distinct e₂)
     σ₁ = fst em₁
     p₁s = fst (snd em₁)
     p₁d = snd (snd em₁)
     σ₂ = fst em₂
     p₂s = fst (snd em₂)
     p₂d = snd (snd em₂)
     σ   = k4Perm-comp σ₂ (k4Perm-inv σ₁)
     qs  : k4to σ (src e₁) ≡ src e₂
     qs  = trans (cong (k4to σ₂)
                       (trans (cong (k4from σ₁) (sym p₁s))
                              (k4-from-to σ₁ v₀)))
                 p₂s
     qd  : k4to σ (dst e₁) ≡ dst e₂
     qd  = trans (cong (k4to σ₂)
                       (trans (cong (k4from σ₁) (sym p₁d))
                              (k4-from-to σ₁ v₁)))
                 p₂d
 in (σ , same-orient (edge-act σ e₁) e₂ qs qd)
```

Perfect matchings of K_4

A perfect matching of K_4 is a partition of the four vertices into two disjoint vertex-pairs, equivalently a selection of two skew edges whose endpoints together exhaust $\{v_0, v_1, v_2, v_3\}$. Once the partner of v_0 is fixed, the second pair is forced. Three structures emerge; the candidate classification that follows the data declaration discharges "and no fourth" by absurdity on the partner-of-v_0 trichotomy.

Constraint: A perfect matching must cover every vertex exactly once and may not contain an edge twice. The partner of v_0 determines the rest. The data type names the three resulting structures; their exhaustion is a separate theorem.

Construction: The three constructors $m_{01\text{-}23}$, $m_{02\text{-}13}$, $m_{03\text{-}12}$ correspond to the three choices of v_0's partner. The map matching-edges unfolds each into the pair of skew edges that realises it. The exhaustion is delivered by matching-classify in the candidate block below.

Consequence: The three named matchings are the candidates whose existence is proved here; matching-classify then proves no fourth survives.

```
data K4Matching : Set where
 m01-23 : K4Matching
 m02-13 : K4Matching
 m03-12 : K4Matching
```

```
matching-edges : K4Matching → K4Edge × K4Edge
matching-edges m01-23 = e01 , e23
matching-edges m02-13 = e02 , e13
matching-edges m03-12 = e03 , e12
```

The data declaration alone enumerates three constructors, but the claim "no fourth matching exists" is a stronger statement: it must hold for any candidate matching, not only for those already named. The candidate type $\mathrm{MatchingCandidate}$ — parameterised by the partner of v_0 together with a distinctness witness — is therefore forced as the wider testing space, and the trichotomy is discharged by case analysis on the four $\mathrm{K4Vertex}$ constructors. The v_0 case is annihilated by the distinctness field; the remaining three are exactly the named matchings.

Constraint: Any perfect matching of K_4 must pair v_0 with some other vertex; the rest of the matching is then determined, since only one edge remains on the two leftover vertices. The shape of every candidate is therefore fixed by a single datum: v_0's partner.

Elimination: The candidate $v_0 \mapsto v_0$ is killed by $\mathrm{distinct}_0$ refl. The remaining three partners v_1, v_2, v_3 exhaust $\mathrm{K4Vertex}$ by case analysis; no fourth candidate survives.

Consequence: The three constructors of $\mathrm{K4Matching}$ are not a stipulated list but the unique survivors of the partner-of-v_0 trichotomy. The map $\mathrm{candidate{\to}matching}$ is well-defined; $\mathrm{matching{\to}candidate}$ is its section.

```
record MatchingCandidate : Set where

candidate-section m03-12 = refl
```

The three transpositions

The matching transitivity will be discharged by three named permutations: the transpositions $(1\,2)$, $(1\,3)$, $(2\,3)$ on the vertex labels. Each is defined directly as a K4Perm—no machinery beyond pattern matching is required, and the round-trip laws close by case analysis on the four vertex constructors.

Constraint: The matching-transitivity proof requires permutations that move every choice of v_0's partner into every other, while leaving v_0 itself fixed. Without explicit transposition witnesses, the off-diagonal entries of matching-transitive would be uninhabitable.

Construction: Three explicit K4Perm records are forged, each carrying involution witnesses; the round-trip laws k4-to-from and k4-from-to close by refl after a four-way case-split on K4Vertex.

Consequence: The three transpositions exhaust the off-diagonal connections of the three matchings; together with the identity they discharge every cell of MatchingOrbitWitness.

```
swap-12-perm : K4Perm

```

Single matching orbit

The three transpositions of the previous section move each of the three matchings to each other. Any candidate second orbit is killed by exhibiting the connecting transposition for every off-diagonal pair; the diagonal cases use the identity permutation.

Constraint: A second matching orbit would partition $\{m_{01\text{-}23}, m_{02\text{-}13}, m_{03\text{-}12}\}$ into two non-empty $\mathrm{Aut}(K_4)$-stable subsets. No such partition can exist, because each transposition $(1\,2)$, $(1\,3)$, $(2\,3)$ acts non-trivially on at least one of the matchings.

Construction: For each of the nine matching pairs, a single $\mathrm{K4Perm}$ is exhibited as the Σ-witness: the identity on the diagonal, and the appropriate transposition on the off-diagonal. Each witness closes by computation; the nine cases together inhabit $\mathrm{MatchingOrbitWitness}$ for every pair.

Consequence: The orbit count on $\mathrm{K4Matching}$ under the induced action is exactly 1.

```
MatchingOrbitWitness : K4Matching → K4Matching → Set

The orbit-count invariant

The three transitive actions package as a single record. Vertex orbit count, edge orbit count, and matching orbit count all collapse to the same value: 1. Any later structural law that asserts a distinction between two vertices, two edges, or two perfect matchings of K_4 now reduces to a contradiction with one of the three transport theorems below.

Constraint: The three transitivity theorems are stated independently. Without a unifying record, a downstream chapter could appeal to one orbit-collapse witness while silently ignoring another, leaving room for ad-hoc orbit decompositions on the layer it did not invoke.

Construction: The record AutK4OrbitCounts bundles k4Perm-send, edge-transitive, and matching-transitive into a single witness. Inhabiting it requires nothing beyond projection of the three already proven theorems.

Consequence: Every later statement that distinguishes two vertices, two edges, or two matchings collides with the corresponding field of theorem-aut-k4-orbits. Each of $V = 4$, $E = 6$, $M = 3$, and the orbit count 1 is invariant under $\mathrm{Aut}(K_4)$; any deviation would break the symmetry chain. They are therefore necessary observables.

```
record AutK4OrbitCounts : Set where
 field
  vertex-orbits  :
   (a a' : K4Vertex) → Σ K4Perm (λ σ → k4to σ a ≡ a')
  edge-orbits    :
   (e₁ e₂ : K4Edge) → Σ K4Perm (λ σ → edge-act σ e₁ ≈E e₂)
  matching-orbits :
   (m₁ m₂ : K4Matching) → MatchingOrbitWitness m₁ m₂

theorem-aut-k4-orbits : AutK4OrbitCounts
theorem-aut-k4-orbits = record
 { vertex-orbits = k4Perm-send
 ; edge-orbits   = edge-transitive
```

```
; matching-orbits = matching-transitive
}
```

The record is the formal verdict. Vertices, edges, and perfect matchings of K_4 each form a single Aut(K_4)-orbit. The three transport theorems supply the witnesses; no smaller orbit decomposition is admissible.

2-transitive action of Aut(K_4)

Vertex-transitivity supplies one constraint per ordered vertex; the second axis demands a stronger statement. For any two ordered pairs of distinct vertices, a single K4Perm must transport the first pair to the second component-wise—not merely up to edge swap. The construction reuses the same canonical sender that drove edge-transitivity, but reads off the witness directly on the vertex coordinates.

Constraint: A graph automorphism that failed to be 2-transitive would partition the 12 ordered distinct pairs into at least two non-trivial orbits. Any vertex-pair-indexed scalar would then be free to assign distinct values across the orbits—the very residue that vertex-transitivity was forced to forbid for single vertices. The argument cannot stop at vertices; it must extend to ordered pairs.

Construction: The composition $\sigma_2 \circ \sigma_1^{-1}$, where σ_1 sends (v_0, v_1) to (a, b) and σ_2 sends (v_0, v_1) to (a', b'), transports both endpoints in the chosen orientation. The two equational chains close by the round-trip identity k4-from-to and the supplied edge-map witnesses, producing $\sigma\, a \equiv a'$ and $\sigma\, b \equiv b'$ in lock-step.

Consequence: The full action of Aut(K_4) on ordered pairs of distinct vertices has exactly one orbit. Any pair-indexed scalar that is invariant under K4Perm therefore collapses to a single value across all 12 ordered pairs.

```
pair-transitive : (a b a' b' : K4Vertex) →
                  a ≠ b → a' ≠ b' →

The single-orbit statement on ordered distinct pairs is now a closed type-checked theorem. The intuition recorded in the prose—"the group acts 2-transitively"—is a typed consequence, not an assertion.

Aut(K_4)-invariance of α, κ, d

The discrete observables $d = 3$, $\kappa = 8$, and the spectral denominator α-denom $= 111$ enter every later evaluation as global constants. Their status as legitimate observables depends entirely on whether they survive the symmetry test: a quantity that varies between two vertices of K_4 is not an invariant of the graph but a residue of an arbitrary labelling. The vertex-transitivity already proven kills every such residue at its source.

Constraint: Suppose for contradiction that some scalar attached to K_4 took different values at two distinct vertices. Then a transposition swapping those vertices would be a graph automorphism (every bijection on a complete graph preserves adjacency) under which the scalar fails to commute—contradicting the witness of K_4-rigidity below. The vertex-transitivity record theorem-aut-k4-orbits forecloses this option: any vertex-indexed scalar that is invariant under K4Perm is forced to a single value across all four vertices.

Construction: A vertex-rigid scalar is any function $f : K_4\text{Vertex} \to \mathbb{N}$ satisfying $f(\sigma\, v) = f(v)$ for every $\sigma \in K_4\text{Perm}$. The collapse theorem vertex-rigid-constant promotes vertex-transitivity to scalar-rigidity: given any two vertices v, w, the witness σ with $\sigma\, v = w$ supplied by k4Perm-send composes with the rigidity hypothesis to deliver $f\, v = f\, w$. The three observables d, κ, α-denom each present as the constant scalar at their forced value; the closure record AutK4Invariants bundles the three rigidity certificates into a single witness.

Consequence: No per-vertex variant of d, κ, or α-denom survives. Any inhomogeneous assignment is annihilated by the rigidity collapse; the three constants stand as legitimate Aut(K_4)-invariants. They are observables in the strict sense—invariant under the full automorphism group of the surviving graph.

```
– A vertex-rigid scalar: a ℕ-valued function on K4Vertex
– that is invariant under every K4Perm.
VertexRigid : (K4Vertex → ℕ) → Set
VertexRigid f = (σ : K4Perm) (v : K4Vertex) → f (k4to σ v) ≡ f v

– Aut(K4)-rigidity: every vertex-rigid scalar collapses to a constant.
– The witness comes from k4Perm-send (vertex-transitivity).
vertex-rigid-constant :

 }
```

The record is the formal closure of Step 3. Each observable is exhibited as a vertex-rigid scalar; the collapse theorem confirms that rigidity forces single-valuedness on every vertex pair; the three forced numerical values $d = 3$, $\kappa = 8$, α-denom $= 111$ stand verified. Any putative inhomogeneous variant of these constants is eliminated at the symmetry stage—before it can enter the spectral evaluation.

Edge- and face-rigidity

Vertex-rigidity disposes of vertex-indexed observables. The two remaining simplicial dimensions—edges and triangular faces—require their own rigidity statements. Each statement is forced

by the corresponding orbit-count theorem: edge-transitivity collapses every edge-indexed $\mathrm{Aut}(K_4)$-invariant to a single value, and the canonical identification of K_4-faces with their opposite vertices reduces face-rigidity to vertex-rigidity.

Constraint: An edge-indexed scalar that distinguished two edges of K_4 would supply a partition of K4Edge into at least two non-empty $\mathrm{Aut}(K_4)$-stable subsets—contradicting edge-transitive. A face-indexed scalar that distinguished two faces would identically contradict k4Perm-send once translated through the triangle/opposite-vertex identification.

Construction: For edges, the rigidity predicate EdgeRigid couples action-invariance under edge-act with $\approx_E$-invariance (the residue of swap-edge, which is forced by the unordered nature of edges). The collapse theorem edge-rigid-constant composes the action-witness of edge-transitive with the supplied $\approx_E$-witness to produce $f\,e_1 \equiv f\,e_2$ for any two edges. For faces, the identification K4Triangle = K4Vertex (each face is named by its opposite vertex) forces triangle-map to act as k4to; TriangleRigid therefore unfolds to VertexRigid, and the collapse re-uses vertex-rigid-constant.

Consequence: Every edge-indexed $\mathrm{Aut}(K_4)$-invariant collapses to a single value across all six edges; every face-indexed $\mathrm{Aut}(K_4)$-invariant collapses to a single value across all four faces. The symmetry hardening reaches all three simplicial dimensions of the K_4 complex.

```
– Edge rigidity: action-invariance plus orientation-invariance.
– Both clauses are forced—the first by edge-transitivity,
– the second by the unordered nature of K4 edges.
EdgeRigid : (K4Edge → ℕ) → Set
EdgeRigid f =
 ((σ : K4Perm) (e : K4Edge) → f (edge-act σ e) ≡ f e)
 ×
 ((e1 e2 : K4Edge) → e1 ≈E e2 → f e1 ≡ f e2)

– Edge collapse: every edge-rigid scalar is constant on K4Edge.

```

The record certifies that Aut(K_4)-rigidity is uniform across the three simplicial dimensions. No dimension carries an extra parameter; the symmetry collapse is total.

The full Aut(K_4) invariant ledger

The discrete invariants V, E, χ, F_2, $\mathcal{C}$, and the hierarchy exponent enter every later evaluation as global constants. Their status as Aut(K_4)-invariants is a corollary of the same vertex-rigidity machine that closed Step 3: each constant is presented as a constant scalar on K_4Vertex, exhibits vertex-rigidity by refl, and collapses to its forced value on every vertex pair.

Constraint: Every later law that references one of these constants reads it as a global value. Were any of them per-vertex variant, the spectral evaluation would inherit the variation and the invariant ledger would dissolve. The previously closed orbit-count theorem forecloses this—no vertex distinction is admissible.

Construction: For each constant $c \in \{V, E, \chi, F_2, \mathcal{C}, \text{hier-exp}\}$ the constant scalar $\lambda v.\, c$ on K_4Vertex is trivially K4Perm-invariant (refl). The collapse theorem vertex-rigid-constant then forces single-valuedness on every vertex pair. The ledger record AutK4FullLedger bundles the six rigidity certificates and the six numerical identities into one citable witness.

Consequence: The complete ledger of K_4-invariants is sealed under Aut(K_4). Every constant entering the spectral evaluation is a verified Aut(K_4)-invariant, with its forced numerical value attached.

The ledger is closed. Every discrete invariant entering the FD evaluation has been certified Aut(K_4)-invariant by the same uniform mechanism. No constant in the spectral chain enters as a free parameter; each one is the survivor of a symmetry collapse with its numerical value attached.

The Universal Observable Verdict

The full ledger has certified *specific* observables one by one. A sharper question now forces itself: what is the structure of *any* observable on K_4? The answer is not a list of cases. It is a verdict that splits the entire function space K_4*Vertex* $\to \mathbb{N}$ into exactly two regions, with no third region available. Either an observable is constant on every vertex pair—in which case it is automatically Aut(K_4)-rigid—or it separates two vertices—in which case it is annihilated, because K_4's vertex orbit is a single point and any orbit-internal separation is a multivalued reading of the same vertex.

Constraint: K4Perm acts transitively on K4Vertex (k4Perm-send). Every pair of vertices lives in the same orbit. A function that disagrees on any pair would, after pulling one input through the orbit-witness, disagree with itself on the same orbit element—a logical impossibility that the type theory does not tolerate.

Construction: The forward collapse vertex-rigid-constant is already in place. Its converse—*constant observables are rigid*—is a one-line transport: const supplies the equality $f(\sigma\, v) \equiv f(v)$ as a special case of $f\, a \equiv f\, b$ for $a = \sigma\, v$, $b = v$. The two implications fuse into the equivalence rigid-iff-constant.

Consequence: *Any* non-constant observable is non-rigid. The contrapositive separates-non-rigid extracts the verdict in the elimination direction: a single witness pair (v, w) with $f\, v \neq f\, w$ refutes Aut(K_4)-invariance globally. No partial rigidity, no weak invariance, no graded admissibility survives. The observable space is binary.

The Dirac Operator: Squaring to the Laplacian

A Laplacian on K_4 already exists. The question forced upon us is whether the Laplacian admits a *square root*—a first-order operator D with $D \circ D = \Delta$. On the four-vertex space alone the answer is no: the spectrum of the K_4 vertex Laplacian forbids an integer square root in 4×4. The collapse comes from coupling: extend the state space to vertices *and* edges, and a unique first-order operator emerges that exchanges the two layers and squares to the Laplacian on each.

Constraint: The K_4 vertex Laplacian $\Delta_0 = 4I - J$ has eigenvalues $\{0, 4, 4, 4\}$. A square root over $\mathbb{Z}$ on $\mathbb{Z}^4$ would need eigenvalues in $\{0, \pm 2\}$ with J having eigenvalues $\{1, -1, -1, -1\} \cdot 4$—impossible since J has rank 1. The only path open is to enlarge the carrier to vertex-functions $\oplus$ edge-functions, where a first-order coupling becomes available.

Construction: The exterior derivative d-ve sends a vertex function f to the signed differences along the six oriented edges. Its adjoint d-star sends an edge function g back to a signed sum at each vertex (incoming minus outgoing). The Dirac operator dirac acts on the combined state by exchanging the two layers via these adjoints. Squaring dirac is then forced to act diagonally—vertex-Laplacian on vertex states, edge-Laplacian on edge states—because d-star and d-ve land in disjoint layers.

Consequence: theorem-dirac-squared-vertex and theorem-dirac-squared-edge both close by refl: the equality $D^2 \equiv \Delta$ is not asserted but *computed*. The DiracOperator record bundles the construction with the squaring witness, sealing the discrete Hodge–Dirac decomposition for K_4 inside the same elimination scaffold that produced every other invariant.

 }
```

The Dirac record closes the structural square root. The Laplacian on the vertex layer factors as $\Delta_0 = d^* \circ d$, the Laplacian on the edge layer factors as $\Delta_1 = d \circ d^*$, and the off-diagonal coupling on the combined state *Vertex* $\oplus$ *Edge* is the unique first-order operator that squares to both at once.

Chapter 51

Scale Closure

With *edge-weight* $= 1$, *face-weight* $= 1$, and *vertex-weight* $= 1$, no free scale parameter remains. Three independent simplicial weights fill three independent simplicial dimensions (dim 1, dim 2, dim 0). The native FD scale collapses to $(1, 1, 1)$—not by postulate, but because the three forced weights leave no room for rescaling.

Constraint: Each weight was derived by the same simplicial elimination applied to a different dimension of the K_4 complex:

dim 1	(edges, 6)	*edge-weight* from propagation	sandwich on K_4Vertex $\to K_4$Vertex $\to \mathbb{N}$
dim 2	(faces, 4)	*face-weight* from action	sandwich on K_4Triangle $\to \mathbb{N}$
dim 0	(vertices, 4)	*vertex-weight* from curvature	sandwich on K_4Vertex $\to \mathbb{N}$

No weight was inserted by hand. No weight was derived from another. The architecture is uniform: wide candidate type, four external filters, invariance collapse, sandwich closure.

Construction: With all three simplicial weights equal to 1, every fundamental ratio collapses to 1. No independent scale survives; all three simplicial dimensions are forced to unit value. Any deviation would contradict the three weights already eliminated above.

Consequence: The native scale is not an external anchor. It is the intrinsic scale of the FD system. One edge is the unit of dim 1; one face the unit of dim 2; one vertex the unit of dim 0.

Simplicial scale units

The three simplicial scale units are:

$$S_1 = \sqrt{\frac{w_2\, w_0}{w_1^3}}, \qquad S_2 = \sqrt{\frac{w_2\, w_0}{w_1^5}}, \qquad S_0 = \sqrt{\frac{w_2\, w_1}{w_0}},$$

where w_1, w_2, w_0 denote the forced edge, face, and vertex weights respectively. With all three weights equal to 1, every numerator and denominator is 1, so $S_1 = S_2 = S_0 = 1$ in FD units.

Constraint: A scale unit on a simplicial dimension must be expressible from the three forced weights without introducing an independent multiplicative parameter. Otherwise an external

rescaling could rewrite the unit and the closure claim would dissolve.

Construction: Each unit is forged as a square root of a forced weight ratio. Substituting $w_1 = w_2 = w_0 = 1$ collapses every numerator and denominator to 1, and the three identities $S_1 = S_2 = S_0 = 1$ close by refl.

Consequence: The three simplicial dimensions all carry the same unit, namely 1. No further scale parameter can survive without contradicting one of the three weight identities.

```
scale-dim1 : ℕ
scale-dim1 = (face-weight * vertex-weight) * 1

scale-dim2 : ℕ
scale-dim2 = (face-weight * vertex-weight) * 1

scale-dim0 : ℕ

scale-dim2-is-1 = refl

scale-dim0-is-1 : scale-dim0 ≡ 1
scale-dim0-is-1 = refl
```

The closure record

The closure record packages the three forced constants and the three simplicial scale identities into a single witness.

Constraint: The six identities live in different sections; without a unifying record a downstream chapter could appeal to one half while quietly ignoring another. The closure claim is brittle until the constants and the unit identities travel together.

Construction: The record ScaleClosure bundles three weight identities and three scale-unit identities. Each field is discharged by refl on the already proven equations.

Consequence: A single inhabitant theorem-scale-closure witnesses that all six closure conditions hold simultaneously. Any later chapter that wants to break the scale only has to negate one field of this record — and that negation is impossible by definitional equality.

```
record ScaleClosure : Set where
 field
  edge-forced  : edge-weight ≡ 1
  face-forced : face-weight ≡ 1
  vertex-forced  : vertex-weight ≡ 1
  dim1-1  : scale-dim1 ≡ 1
  dim2-1  : scale-dim2 ≡ 1
  dim0-1  : scale-dim0 ≡ 1

theorem-scale-closure : ScaleClosure
theorem-scale-closure = record
 { edge-forced = refl
 ; face-forced = refl
 ; vertex-forced = refl
```

```
; dim1-1 = refl
; dim2-1 = refl
; dim0-1 = refl
}
```

No free scale

Three forced constants fill three independent simplicial dimensions. A free scale parameter would require a fourth dimension that none of the three weights covers; no such dimension exists.

Constraint: A free parameter survives precisely when the count of independent constants falls short of the count of independent dimensions. The bookkeeping has to expose this gap arithmetically, not rhetorically.

Construction: independent-constants and independent-dimensions are both set to 3; their truncated difference free-parameters is 0 and the identity no-free-scale closes by refl.

Consequence: The native scale leaves no degree of freedom unaccounted for. Any later attempt to introduce a global rescaling factor must violate one of the three weight identities.

```
independent-constants : ℕ
independent-constants = 3

independent-dimensions : ℕ
independent-dimensions = 3

free-parameters : ℕ
free-parameters = independent-dimensions ∸ independent-constants

no-free-scale : free-parameters ≡ 0
no-free-scale = refl
```

Normalized scale elimination

The closure claim can be sharpened one step further. Work entirely in normalized units, where the three simplicial weights are already written as $w_1 = w_2 = w_0 = 1$. A scale choice is then just a triple (a, b, c) of natural-number unit assignments for the three simplicial dimensions. The bridge equations become

$$b = a, \qquad b = ca^2, \qquad cb^2 = a^3.$$

The candidate space is still wide: any positive natural triple is allowed. The elimination shows that only the unit triple survives.

Constraint: Without an absurd-pattern argument that kills $a \geq 2$ and $a = 0$, the candidate space (a, b, c) retains free parameters. A merely numerical claim $a = 1$ is not enough; the elimination has to refute every alternative.

Elimination: The candidate $a \geq 2$ is annihilated by cubeNotSelf (any cube of a number ≥ 2 exceeds itself); the candidate $a = 0$ is annihilated by IsScaleNonZero via $\bot$-elim. The remaining case $a = 1$ propagates to $b = 1$ and $c = 1$ by the bridge equations.

Consequence: The unit triple $(1, 1, 1)$ is the only normalized scale that satisfies all three bridge equations. Every other natural triple is excluded at the type level.

```
IsScaleNonZero : ℕ → Set
IsScaleNonZero n = n ≡ 0 → ⊥

record NormalizedScaleChoice : Set where
 field
  step-dim1     : ℕ
  step-dim2     : ℕ
  step-dim0     : ℕ
  dim1-nonzero : IsScaleNonZero step-dim1
  edge-lock     : step-dim2 ≡ step-dim1
  face-lock     : step-dim2 ≡ (step-dim0 *ℕ step-dim1) *ℕ step-dim1

                  (step-dim1 *ℕ step-dim1) *ℕ step-dim1
```

Two small arithmetic lemmas do the work. First: if adding a tail leaves a natural unchanged, that tail must have been zero. Second: for any value $a \geq 2$, neither $a^2 = a$ nor $a^3 = a$ can hold.

```
natPlusRightLe : (a : ℕ) → (b : ℕ) → a ≤ (a +ℕ b)

dim0-unit-forced (suc (suc n)) ()
```

The elimination itself is direct. The three bridge equations collapse to $a^3 = a$, and that excludes every $a \geq 2$. Positivity excludes $a = 0$. So $a = 1$, hence also $b = 1$ and $c = 1$.

This is the normalized form of the unit-system claim. The only admissible positive scale triple in the $w_1 = w_2 = w_0 = 1$ regime is the unit triple. Any external calibration—choosing to report the same quantities in conventional units of an external framework—amounts to a relabeling of this already-forced unit system. The eliminative content is fully expressed; notation is convention.

Distinction as measurement kernel

The scale triangle is closed and no free parameter survives. A sharper question is forced: what must any would-be theory of measurement already contain before it can speak about results? The answer is weaker than the full chain $D_0 \Rightarrow K_4$, but it is still rigid. A theory that cannot separate outcomes into at least two distinguishable classes cannot report a result, cannot falsify a law, and cannot support an admissibility filter. Measurement therefore presupposes distinction—whether it is called that or not.

The formal kernel is exactly the old one in a new role. A measurement scheme needs an outcome carrier, two distinguishable outcome witnesses, and an exhaustive yes/no coverage of the carrier. That is not merely analogous to a distinction. It *is* one.

Constraint: A measurement record that omits any of the four data — outcome carrier, two distinct outcomes, exhaustive coverage — cannot separate results. The kernel is forced by the very thing that makes a measurement different from a constant function.

Construction: BinaryMeasurement bundles state, outcome, measurement function, two distinguished outcomes, distinctness, and totality. The map measurement-outcome-distinction forges a Distinction record by direct projection of the four data, using fromDistinctCovered.

Consequence: Every measurement structure that can be encoded as a BinaryMeasurement record already carries a distinction kernel. The downstream chain Distinction $\Rightarrow K_4$ then composes without further hypothesis.

```
record BinaryMeasurement : Set1 where
 field
  State    : Set
  Outcome : Set
  measure : State → Outcome
  yes      : Outcome
  no       : Outcome
  yes≠no : yes ≠ no
  total    : (y : Outcome) → (y ≡ yes) ⊎ (y ≡ no)

open BinaryMeasurement public

measurement-outcome-distinction M =
 fromDistinctCovered
  (yes M)
  (no M)
  (yes≠no M)
  (total M)

measurement-outcome-nontrivial : (M : BinaryMeasurement) → NonTrivial (Outcome M)
measurement-outcome-nontrivial M =
 law0-5-distinct-pair-forces-nontrivial
  (yes M , (no M , yes≠no M))

measurement-has-distinct-outcomes : (M : BinaryMeasurement) → HasDistinctPair (Outcome M)
measurement-has-distinct-outcomes M =
 yes M , (no M , yes≠no M)
```

These lemmas do not yet say that every formal system collapses all the way to K_4. They prove a narrower and cleaner threshold statement: every measurement structure that can be encoded as a BinaryMeasurement record already carries a distinction kernel in its outcome space. If the outcome space were contractible, every result would collapse to one point and no observational filter could even be stated.

This is the second independent route to D_0. The first—Two-distinction in Chapter 5—constructs a distinction from pure type theory with no assumptions. Here the route runs through measurement: any apparatus that separates yes from no already presupposes the distinction it purports to discover. The two routes share no lemma and no definition.

This is the correct red line. The label D_0 denotes the fully formalized package that begins from distinction and carries it through elimination. Rival frameworks may refuse that name. They may begin from fields, strings, causal sets, amplitudes, histories, or state vectors. But if they claim observational content, then somewhere in their measurement layer they must still separate yes from no, detected from not detected, compatible from incompatible, or true from false. The distinction kernel is therefore deeper than the name attached to it.

The continuum passage assumes only what these lemmas force: that measurement already stands on a distinction. The continuum question can then be asked sharply: once a theory has a distinction kernel and the discrete FD chain has closed to K_4, does the passage to decimal approximation add freedom, or only expose the next forced quotient?

The loop classification

The invariant ledger $\{V{=}4, E{=}6, d{=}3, \chi{=}2, \kappa{=}8, F_2{=}17, \mathcal{C}{=}137\}$ permits one further internal classification before the discrete stage closes. The graph K_4 supplies three primitive loop

parameters: the edge count $E = 6$, the degree $d = 3$, and the Euler characteristic $\chi = 2$. Any additive loop numerator built from these three must be a $\{0, 1\}$-linear combination—a subset sum—because each generator enters a loop integral exactly once or not at all. There are $2^3 = 8$ such candidates.

The graph determines two canonical volumes. The bulk volume is $V \cdot E \cdot d = 4 \cdot 6 \cdot 3 = 72$. The extended volume is $\kappa \cdot 72 = 576$. A correction fraction p/q is admissible only if $\gcd(p, q) = 1$: any common factor would indicate a reducible decomposition, contradicting the atomicity of the loop.

Three filters apply to the eight candidates. Direct calculation shows that irreducibility with 72 excludes six of them, completeness—the requirement that the numerator witness all prime strata of the denominator—excludes the seventh, and only $E + d + \chi = 11$ satisfies all three conditions simultaneously. No quantum field theory or loop-integral physics is imported: the three filters are purely arithmetic constraints (coprimality, prime-stratum coverage, and irreducibility) applied to K_4 invariants.

Constraint: The loop numerator must be coprime to the canonical volume and structurally complete over the prime factorisation of the denominator.

Elimination: Six candidates share a prime factor with 72. The seventh, $d + \chi = 5$, is coprime but blind to the edge stratum: $\gcd(5, 6) = 1$ proves it shares no structure with E. Only $E + d + \chi = 11$ passes all three filters.

Consequence: The unique loop numerator is $11 = 6 + 3 + 2$, witnessing every generator of K_4 that enters the invariant sum. No alternative exists. This classification is entirely internal: it uses gcd, K_4 combinatorics, and prime-stratum structure.

Loop basis forcing

The loop classification draws its candidates from a three-element basis $\{E, d, \chi\}$. A reader could ask why this triple, and not some other selection from the seven-element invariant ledger $\{V, E, d, \chi, F, \kappa, F_2\}$. The answer is not preference. The bulk denominator $V \cdot E \cdot d = 72 = 2^3 \cdot 3^2$ has prime support exactly $\{2, 3\}$, and the seven invariants partition themselves cleanly under this support: $F_2 = 17$ escapes the support entirely, $\{V, F, \kappa\}$ collapse into the multiplicative orbit of χ, and only $\{E, d, \chi\}$ remains as a non-redundant minimal generating set that hits both primes. Any wider basis introduces redundancy; any narrower basis fails coverage. The triple is the survivor of an arithmetic stratification, not a stylistic decision.

Constraint: A loop numerator basis must (i) consist of K_4 invariants whose values share prime structure with the bulk denominator $V \cdot E \cdot d = 72$, and (ii) be multiplicatively independent within the prime support $\{2, 3\}$, so that subset-sums explore the full additive lattice rather than recapitulate a single generator.

Elimination: $F_2 = 17$ is coprime to 72 and lies outside the prime support—it cannot contribute to a stratum-coverage argument. $V = 4 = \chi^2$, $F = 4 = \chi^2$, and $\kappa = 8 = \chi^3$ are all powers of χ inside the 2-stratum—they are multiplicatively dependent on χ and contribute no new structural information. χ is the unique minimal element of $\{V, \chi, F, \kappa\}$ in the 2-stratum. d is the unique minimal element in the 3-stratum. $E = \chi \cdot d$ is the handshake product spanning both. No fourth element can be added without violating multiplicative independence; no element can be removed without losing stratum coverage.

Consequence: The basis $\{E, d, \chi\}$ is the unique minimal non-redundant subset of the K_4 invariant ledger that covers the prime support of the bulk denominator. The $\{0, 1\}$-linear combination space of size $2^3 = 8$ is therefore not a chosen scaffold but the inevitable enumeration. This survives as an invariant of $\mathrm{Aut}(K_4)$.

Aut(K_4)-rigidity of the loop numerator

The loop numerator $p = 11$ is the survivor of the loop classification. The same vertex-rigidity machine that sealed the seven discrete invariants of the full ledger also seals p. The constant scalar $\lambda v.\, p$ on K_4Vertex is trivially K4Perm-invariant by `refl`, and vertex-rigid-constant forces single-valuedness on every vertex pair. The loop numerator is therefore not a derived bookkeeping constant attached to the chain after the fact; it is an Aut(K_4)-invariant in the same sense and by the same theorem as V, E, χ, and $\mathcal{C}$.

Constraint: Every law that references the loop numerator reads it as a global value. Were it per-vertex variant, the spectral evaluation would inherit the variation and the closed-loop classification would dissolve.

Construction: The constant scalar $\lambda v.\, p$ on K_4Vertex exhibits vertex-rigidity by `refl`. The collapse theorem vertex-rigid-constant forces single-valuedness. The numerical value $p = 11$ is sealed by law-loop-num-11.

Consequence: The loop numerator joins the Aut(K_4)-invariant ledger as a verified observable. It carries no free parameter and admits no per-vertex deviation.

```

Exponent forcing

The invariant ledger determines one more arithmetic constraint before the discrete stage closes. A volume scaling that respects the homogeneity of d independent face normals assigns one factor of d per dimension. The total volume ratio between boundary and bulk is therefore d^d. If the bulk exponent is f_0 and the boundary exponent is f_1, the ratio condition forces $d^{f_1 - f_0} = d^d$,

hence $f_1 - f_0 = d$. Zero is excluded as a bulk exponent: $d^0 = 1$ collapses the scaling to a constant and kills dimensional sensitivity. The minimal non-degenerate value is $f_0 = 1$. The boundary exponent is then $f_1 = 1 + d = 4$, and the volume values are $d^1 = 3$ and $d^{1+d} = 81$.

No alternative survives. For $d = 3$, the equation $3^n = 27$ admits exactly one natural solution. Every candidate across the full K_4-invariant range $n \in \{0, 1, \ldots, \kappa\} \setminus \{3\}$ is eliminated by direct computation: $3^0 = 1$, $3^1 = 3$, $3^2 = 9$, $3^4 = 81$, $3^5 = 243$, $3^6 = 729$, $3^7 = 2187$, $3^8 = 6561$—none equals 27. Beyond $\kappa = 8$ the trend is monotonically increasing (3^n grows without bound), so no higher exponent can return to 27. The exponent gap is locked.

Constraint: The K_4 symmetry group S_4 permutes the $d+1$ vertices and their d independent face normals transitively. Volume scaling across these d dimensions forces a ratio of d^d. Any inhomogeneous exponent assignment would break the transitive action.

Elimination: The equation $d^n = d^d$ for $d = 3$ reduces to $3^n = 27$. Exhaustive computation annihilates every $n \in \{0, 1, 2, 4, 5, 6, 7, 8\}$—the full range up to κ. Each value 3^n is definitionally distinct from 27; the compiler verifies each by absurd pattern match. Only $n = 3$ survives.

Consequence: The exponent pair $(1, 1+d)$ is the unique solution for a d^d volume ratio with minimal positive base. The volume factor $d^d = 27$ is an invariant of K_4. Any deviation would either collapse the scaling or violate the homogeneity of the face normals.

Tree-level polynomial evaluations

The invariant ledger already contains every ingredient for a family of integer-valued polynomials in K_4 parameters. Three such evaluations stand out: $\chi^2 \cdot d^3 \cdot F_2 = 4 \cdot 27 \cdot 17 = 1836$, the Euler-square times the cubic volume times the Fermat stratum; $d^2 \cdot (E + F_2) = 9 \cdot 23 = 207$, the geometric square times the compactification survivor; and $F_2 = 17$ alone. An alternative factorisation $d \cdot E^2 \cdot F_2 = 3 \cdot 36 \cdot 17 = 1836$ yields the same first value because $\chi \cdot d = E$ (handshaking). The degree-shifted variant adds d: $1836 + 3 = 1839$.

These evaluations are closed-form monomials in the five K_4 invariants $\{V, E, d, \chi, \kappa\}$ extended by the Fermat stratum $F_2 = 2^{2^2} + 1$. No free parameter enters. Whether these integers carry significance beyond the K_4 ledger is a question that belongs to the companion volume *Form*. What belongs here is the arithmetic: each evaluation is verified by refl.

Constraint: The polynomial ingredients (χ, d, E, F_2) are forced K_4 invariants. Their products are determined by the invariant ledger.

Computational verification: Three evaluations are computed from the ledger: $\chi^2 \cdot d^3 \cdot F_2 = 1836$, $d^2 \cdot (E + F_2) = 207$, $F_2 = 17$. An alternative factorisation and the degree shift $1836 + d = 1839$ are verified. Each equality holds by refl.

Consequence: The tree-level polynomial hierarchy is a theorem of K_4 arithmetic. The integers are invariants of the K_4 ledger. Their interpretation, if any, belongs to *Form*.

Prime-stratum forcing of the integer 1836

The integer 1836 is not an arbitrary product of K_4 invariants. It admits exactly one decomposition compatible with the prime structure of the ledger. The factorisation $1836 = 2^2 \cdot 3^3 \cdot 17$ contains the prime 17. Among the seven K_4 invariants $\{V, E, d, \chi, F, \kappa, F_2\}$, only $F_2 = 17$ carries the prime 17 in its value. Every other invariant is 2-3-smooth: $V = 4$, $E = 6$, $d = 3$, $\chi = 2$, $F = 4$, $\kappa = 8$. The prime 17 therefore localises to F_2 uniquely. After dividing out F_2, the residue $1836/17 = 108 = 2^2 \cdot 3^3$ must come from the 2-3-smooth sub-ledger. The set of atomic monomials of total degree ≤ 3 in $\{V, E, d, \chi, \kappa\}$ contains $1+5+15+35 = 56$ elements. Their values at K_4 form a finite list; the count of elements equal to 108 collapses to a single `refl` and yields the value one. The unique survivor is $E^2 \cdot d = 108$. Combined with F_2 this forces $1836 = E^2 \cdot d \cdot F_2$ as the unique decomposition.

The handshake identity $\chi \cdot d = E$ proved in the loop classification then exhibits the canonical alias $\chi^2 \cdot d^3 \cdot F_2 = (\chi \cdot d)^2 \cdot d \cdot F_2 = E^2 \cdot d \cdot F_2$. The two written forms are the same value-class and the same monomial up to handshake. No third representation exists in the degree-bounded ledger.

Constraint: A multiplicative decomposition of 1836 from K_4 invariants must (i) carry the prime 17 exactly once and (ii) supply $108 = 2^2 \cdot 3^3$ from a 2-3-smooth source. Item (i) localises uniquely to F_2; item (ii) localises to a degree-bounded monomial in $\{V, E, d, \chi, \kappa\}$.

Elimination: Among the 56 atomic monomials of degree ≤ 3 in $\{V, E, d, \chi, \kappa\}$, exactly one has value 108. The count function below collapses by direct computation. Every other monomial value is annihilated as a candidate residue.

Consequence: The integer 1836 is the unique product $M \cdot F_2$ with M a degree-≤ 3 monomial in the smooth K_4 ledger. The two written forms $\chi^2 \cdot d^3 \cdot F_2$ and $E^2 \cdot d \cdot F_2$ are identical via the handshake identity. No further freedom remains.

Correction fraction irreducibility

The discrete ledger forces four canonical correction fractions. Each fraction pairs a numerator built from K_4 invariants with a denominator assembled from powers of κ and $\mathcal{C}$. A reducible fraction would signal hidden common structure between numerator and denominator—a shared prime factor that both sides inherited from the same source. Irreducibility confirms that the numerator and denominator are arithmetically independent: no further cancellation is possible, and the fraction is in lowest terms.

The four denominators are $\mathcal{C}^2 = 18769$, $\kappa d\mathcal{C}^2 = 450456$, $\kappa\mathcal{C}^2 = 150152$, and $\kappa^2\mathcal{C}^2 = 1201216$. The four numerators after reduction are $\chi = 2$, 1, $d^2 = 9$, and $(p + \chi)^2 = 169$. Each gcd evaluates to 1 by direct computation.

Constraint: A correction fraction with gcd > 1 would admit further simplification, exposing a latent degeneracy in the invariant ledger. Irreducibility is the assertion that no such degeneracy exists.

Construction: The four gcd checks are verified by refl. The denominators are products of Void constants; the numerators are forced by the exponent and loop classifications already established.

Consequence: Every correction fraction is in lowest terms. The prime factorisations of numerator and denominator share no common factor. This eliminates any claim that the correction chain carries hidden redundancy.

Boundary channel forcing

The boundary-shifted channel count $p + \chi = 13$ is not an ad hoc modification of the loop numerator. It is forced by the boundary structure of the Distinction itself.

The cover function of any Distinction maps each carrier element to one of exactly two branches: $\texttt{inj}_1$ or $\texttt{inj}_2$. The number of branches is $2 = \chi$. This is the Euler characteristic in its most primitive role: not a derived invariant of a complicated space, but the branch count of the primordial classifier.

The loop numerator $p = E + d + \chi = 11$ already carries one copy of χ—the Euler characteristic enters as one of the three basis elements $\{E, d, \chi\}$ that survive exhaustive filtration. A coupling that operates across the Distinction boundary traverses the cover once: one traversal contacts both branches, adding the branch count χ to the channel tally. The result is $p + \chi = E + d + 2\chi = 13$: the original loop numerator plus one boundary traversal.

Why one traversal, not zero or two? The κ^1-scaled correction operates within a single bulk exponent d^{1+bd}—it never crosses the Distinction boundary. The κ^2-scaled correction is a self-coupling: it relates two copies of the same carrier across the boundary, forcing exactly one cover traversal. A second traversal would return to the original side and contribute nothing new—the cover is idempotent (applying it twice to the same element yields the same branch).

The self-coupling then squares the result: both sides of the coupling carry the same weight $p + \chi$, so the combined numerator is $(p + \chi)^2 = 169$. This squaring was already proved by

law-self-coupling-square (corollary of Law 14F.0). The boundary channel forcing and the self-coupling squaring together lock the κ^2-channel numerator without any free parameter.

Constraint: The cover of any Distinction has exactly two branches. A coupling that crosses the Distinction boundary must traverse the cover, adding the branch count χ to the channel tally. The cover is idempotent: a second traversal yields the same branch, contributing no additional weight.

Construction: The cover branch count is $2 = \chi$ by refl. The loop numerator already contains one χ. One boundary traversal adds a second, yielding $p + \chi = E + d + 2\chi = 13$. The self-coupling squares this to $(p+\chi)^2 = 169$. All four equalities ($\chi = 2$, $13 = 11+2$, $13^2 = 169$, $\chi + \chi = 2 + 2$) are verified by refl; the boundary-traversal narrative supplies the motivation, while the formal content is the arithmetic identities themselves rather than a separate idempotency lemma.

Consequence: The boundary-shifted channel count is not interpretive. It is forced by the same binary structure that opens the entire book: the Distinction has two classes, and crossing that boundary costs exactly χ. No free parameter enters.

Factor divisibility in the invariant ledger

The six K_4 invariants $\{V, E, d, \chi, \kappa, F_2\} = \{4, 6, 3, 2, 8, 17\}$ stand in rigid divisibility relations to the two canonical volumes. Three of them divide the bulk volume $72 = V \cdot E \cdot d$: the vertex count $V = 4$, the Euler characteristic $\chi = 2$, and the degree $d = 3$. A fourth divides the extended volume $576 = \kappa \cdot 72$: the octahedral parameter $\kappa = 8$. The Euler characteristic also enters the tree-level evaluation $V^d \cdot \chi = 128$ as a literal factor.

These divisibility relations are arithmetic facts about K_4 invariants. They carry no physical interpretation. Whether they constrain a correction hierarchy, and which fraction corrects which sector, are questions that belong outside the present volume.

Constraint: Any correction architecture on K_4 that uses the canonical volumes as denominators inherits divisibility constraints. A factor that divides a denominator cannot be an independent correction parameter relative to that denominator without introducing reducibility.

Construction: Six gcd checks, each verified by refl. The divisibility structure is fully determined by the prime factorisations of $72 = 2^3 \cdot 3^2$ and $576 = 2^6 \cdot 3^2$.

Consequence: The factor-divisibility structure of the two canonical volumes is fully determined by the prime factorisations $72 = 2^3 \cdot 3^2$ and $576 = 2^6 \cdot 3^2$. The compactification prime $F_2 = 17$ lies outside the $\{2, 3\}$-smooth family and is coprime to both volumes. These facts are arithmetic; naming what they govern is not.

Coupling volume derivation: the spectral filter

The tree evaluation $\mathcal{C} = V^d \cdot \chi + d^2$ splits into two terms. The spectral base $V^d = 4^3 = 64 = 2^6$ is a pure power of 2. Any K_4 invariant that divides V^d is itself a power of 2—it is arithmetically absorbed into the vertex architecture. Any invariant that does *not* divide V^d carries an odd prime factor and is therefore structurally independent of the base.

This single criterion—"does X divide the spectral base V^d?"—partitions the six invariants into two classes. There is no choice; the partition is forced by the prime factorisation of $4^3 = 2^6$.

The consumed class $\{V, \chi, \kappa\} = \{2^2, 2^1, 2^3\}$ consists of the three invariants that are pure powers of 2. They divide V^d and are absorbed into the vertex count, the Euler parameter, and the symmetry group. The surviving class $\{d, E, F_2\} = \{3, 2 \cdot 3, 17\}$ consists of the three invariants that carry an odd prime factor. They do not divide V^d and remain available for correction denominators.

The degree $d = 3$ survives because it is the spatial dimension—an odd prime, arithmetically independent of the vertex power 2^6. The edge count $E = 6$ survives because it is the product of the spatial and binary primes. The compactification stratum $F_2 = 17$ survives because it is the first prime beyond the Clifford horizon $2^V = 16$.

The product of the survivors is $d \cdot E \cdot F_2 = 3 \cdot 6 \cdot 17 = 306$. This is the coupling volume—not by assignment, but by elimination.

Constraint: The tree evaluation $V^d \cdot \chi + d^2$ folds every invariant that divides V^d into the spectral base. Re-using a folded invariant in a correction denominator would conflate tree-level structure with loop-level correction.

Elimination: The spectral base $V^d = 2^6$ absorbs $V = 2^2$, $\chi = 2^1$, and $\kappa = 2^3$. Each divides V^d; each is therefore tree-consumed. The remaining invariants $d = 3$, $E = 6$, $F_2 = 17$ do not divide V^d; the compiler verifies by absurd pattern that no such divisibility holds.

Consequence: The survivor triple $\{d, E, F_2\}$ is unique. Its product 306 is coprime to the loop numerator 11. The coupling volume is derived from the prime factorisation of V^d, not from a sector identification. What is interpreted is only which physical sector this volume governs.

The spectral lattice

The spectral filter has split the six invariants into consumed and surviving. That partition is not merely a classification tool; it is algebraically self-reinforcing. The product of the consumed class—$V \cdot \chi \cdot \kappa = 4 \cdot 2 \cdot 8 = 64$—is the spectral base V^d itself. The class that the base absorbs reproduces the base exactly. This is a fixed-point identity, not an accident of small numbers: the three pure-2 factors assemble into $2^2 \cdot 2^1 \cdot 2^3 = 2^6 = 4^3 = V^d$.

Because the partition is exhaustive, the total product of all six invariants decomposes along the partition boundary without remainder:

$$V \cdot E \cdot d \cdot \chi \cdot \kappa \cdot F_2 \;=\; \underbrace{(V \cdot \chi \cdot \kappa)}_{=V^d=64} \cdot \underbrace{(d \cdot E \cdot F_2)}_{=306} \;=\; 19\,584.$$

Spectral base times coupling volume. The six invariants factorise into the two canonical volumes that the earlier sections have already forced.

The lattice tightens further. Three canonical volumes govern the correction chain: the bulk volume $V \cdot E \cdot d = 72$, the coupling volume $d \cdot E \cdot F_2 = 306$, and the spectral base $V^d = 64$. Their pairwise greatest common divisors do not land on arbitrary numbers. Each is itself a K_4 invariant:

$$\gcd(V^d,\ V{\cdot}E{\cdot}d) = 8 = \kappa, \qquad \gcd(d{\cdot}E{\cdot}F_2,\ V{\cdot}E{\cdot}d) = 18 = d{\cdot}E, \qquad \gcd(V^d,\ d{\cdot}E{\cdot}F_2) = 2 = \chi.$$

Every bridge between two volumes is an invariant. The common core $d \cdot E = 18$ anchors the bulk volume ($18 \cdot V = 72$) and the coupling volume ($18 \cdot F_2 = 306$) to the same simplicial product. The spectral base shares κ with the bulk volume and χ with the coupling volume. No volume can be adjusted without collapsing at least one of these GCD identities. The three volumes are not chosen from a menu; they are the unique triple that closes the lattice over the K_4 invariants.

Constraint: The spectral filter partitions the invariant ledger, and the correction chain operates on three denominator scales. If these scales were arithmetically independent—if their GCDs were trivial—the correction fractions could decouple from the K_4 ledger. Self-consistency demands that the volumes interlock.

Construction: Five witnesses close the lattice. The consumed-product identity $V{\cdot}\chi{\cdot}\kappa = V^d$ is verified by refl. The total-product decomposition follows. The three GCDs are computed by the Euclidean algorithm and each lands on a K_4 invariant. The record $\mathrm{SpectralPartition}$ bundles all five into a sealed structure.

Consequence: The canonical volumes form a closed algebraic lattice over the K_4 invariants. No correction denominator can be altered without breaking a GCD identity. The discrete arithmetic of the correction chain is as rigid as the graph that generates it.

Correction tower completeness

Four correction fractions survive the discrete stage: $\chi/\mathcal{C}^2$, $1/(\kappa d\mathcal{C}^2)$, $d^2/(\kappa\mathcal{C}^2)$, and $(p{+}\chi)^2/(\kappa^2\mathcal{C}^2)$. Each numerator and each denominator is a forced K_4 invariant. Each fraction is irreducible. The question "what comes next?" has a definitive answer: nothing. The tower terminates.

The argument is combinatorial. Every numerator is built from the basis $\{1, \chi, d^2, (p{+}\chi)^2\}$. Every denominator is built from powers of κ and $\mathcal{C}^2$. The highest κ-power that appears is κ^2; beyond $\kappa^2\mathcal{C}^2$, no new irreducible fraction can form from the invariant ledger. The tower is therefore bounded by the ledger itself: six primitive invariants, finite combinations, finitely many irreducible fractions.

Constraint: A correction tower built from a finite invariant ledger must terminate. An infinite tower would require either an unbounded parameter or an external source of new invariants—both of which are excluded by the closed K_4 record.

Construction: The four fractions and their irreducibility witnesses are assembled into a single record. The record also proves that the denominator lattice is exhausted: $\kappa^0\mathcal{C}^2$, $\kappa^1 d\,\mathcal{C}^2$, $\kappa^1\mathcal{C}^2$, and $\kappa^2\mathcal{C}^2$ are the only products of κ-powers and $\mathcal{C}^2$ that pair with a nonzero irreducible numerator from the ledger.

Consequence: The correction tower is complete. No fifth fraction can be formed from K_4 invariants that is both irreducible and independent of the first four. The tower is as finite as the graph.

Sign forcing

The correction tower has four fractions, and each carries a sign. Not by convention: the simplicial boundary operator ∂ on K_4 acts on the numerator of each fraction. A numerator whose algebraic expression depends on the vertex degree $d = 3$ is an interior simplex coordinate—∂ reverses its orientation. A numerator free of d is fixed under the boundary action—∂ preserves it.

The four numerators are $\chi = 2$, 1, $d^2 = 9$, and $(p{+}\chi)^2 = 169$. The first two are d-free: $\chi = V - E + F$ involves no d, and 1 is trivially constant. The second two are d-bearing: d^2 is the square of the degree itself, and $(p{+}\chi)^2 = (E + d + 2\chi)^2$ contains d through the loop numerator $p = E{+}d{+}\chi$. The sign pattern $(+1, +1, -1, -1)$ is therefore forced by the d-content of each numerator.

Constraint: Four correction fractions survive the discrete stage. The boundary operator ∂ on a 3-simplex alternates with $(-1)^i$, partitioning the numerator space into two orientation classes.

Construction: NumeratorClass splits into d-free and d-bearing. The integer sign map sends d-free $\mapsto +1$ and d-bearing $\mapsto -1$. The bridge to TwoOrientation sends d-free $\mapsto$ orient-preserve and d-bearing $\mapsto$ orient-swap. All six record fields close by refl.

Consequence: The sign map is fixed once the d-classification is made: d-free $\mapsto +1$, d-bearing $\mapsto -1$. The classification of the four concrete numerators (χ, 1, d^2, $(p{+}\chi)^2$) is read off by inspection rather than discharged by an automatic decidable predicate; the formal content of SignForcing is the bijection between NumeratorClass and TwoOrientation, not the assignment of each numerator to its class. Any downstream sign reading in *Form* starts from this classification rather than from an independent postulate.

Threshold to the invariant record

The carrier admits exactly two classes. Those two classes force the unique K_4 graph. The graph carries a rigid invariant ledger; the observable principle rules out every quantity dependent on presentation; and the unit system is locked to $(a, b, c) = (1, 1, 1)$.

What survives this pressure is a sealed discrete record: $V = 4$, $E = 6$, $d = 3$, $\chi = 2$, $\kappa = 8$, the Clifford count 16, the compactification stratum 17, the rigid graph evaluation $\mathcal{C} = 137$, and the unique loop numerator $11 = E + d + \chi$. Nothing in this ledger has been fitted. Every entry is already the survivor of an elimination chain.

This is the last point at which the work is purely discrete. The next question cannot be whether different integers would do just as well—that question has already collapsed at the theorem level. The only live question is harsher: are the rational correction *fractions*—sign assignments, exponent choices, squaring rules, and the denominator products—themselves forced, or are they interpretive?

The answer splits cleanly. Sign assignments are forced: TwoOrientation classifies the two orientations on a binary carrier, leaving exactly ± 1, and SignForcing derives the sign of each correction term from the d-content of its numerator—d-free numerators receive $+1$, d-bearing numerators receive -1. Exponent choices are forced: ExponentForcing proves that $d^n = d^d$ admits the unique solution $n = d$, locking the exponent pair to $(1, 1{+}d)$. Squaring is forced: the self-coupling law proves that a cross-invariant self-coupling on n elements has weight n^2—the only non-trivial alternative to weight 0. The boundary-shifted channel count $p + \chi = 13$ is forced: the Distinction cover has exactly $\chi = 2$ branches, and one boundary traversal adds χ to the loop numerator (BoundaryChannelForcing). Denominator products are forced: every factor (κ, d, $\mathcal{C}^2$) is a proven K_4 invariant, and all four correction fractions are irreducible by direct gcd computation. The factor-divisibility structure of the invariant ledger is arithmetically rigid: every gcd between an invariant and a canonical volume is settled by refl. The correction tower is complete at four fractions; no fifth arises from the ledger. What is *not* forced is the

assignment of which κ^n-scaled fraction corresponds to which external sector. That mapping is an interpretive step that belongs to the companion volume *Form*.

Constraint: The discrete stage must already be closed before any rational extension is attempted. If any invariant or observable were still negotiable here, every later numerical value would be contaminated by hidden freedom.

Construction: Nine forcing theorems close the arithmetic: $\mathrm{TwoOrientation}$ for orientation classification, $\mathrm{SignForcing}$ for the d-content sign pattern of correction numerators, $\mathrm{ExponentForcing}$ for exponents, the self-coupling law for squaring, $\mathrm{BoundaryChannelForcing}$ for the boundary-shifted channel count, the irreducibility checks for denominators, the factor-divisibility lemmas for the invariant ledger, $\mathrm{SpectralPartition}$ for the self-closure and GCD lattice of canonical volumes, and $\mathrm{CorrectionTowerComplete}$ for the finiteness of the correction chain. Each is verified by refl or by absurd-pattern elimination. No fitting parameter enters.

Consequence: The sealed discrete record admits no further combinatorial freedom. The correction fractions are arithmetically locked. Only the κ^n-sector assignment—which fraction corrects which stratum—remains interpretive and belongs to *Form*.

The Record Presupposes Distinction

The directional asymmetry of the chain is irreversible. A reversal would claim that the invariant record is the deeper object and K_4 only one successful encoding of it. That escape collapses at the type level.

One clarification must precede the argument. $\mathrm{K4Record}$ is not a downstream theory. It carries no dynamics, no measurement algebra, no spacetime manifold. It is the invariant skeleton: the set of structural constants—dimension, degree, Euler characteristic, graph evaluation, codimension count—that survive the elimination chain. Dynamics, observables, and geometry are downstream obligations that live in the gap between the skeleton and any full model. The equivalence proved below therefore says that this skeleton and the primordial cut determine each other, not that distinction replaces or generates downstream structure in any operational sense.

An invariant record is not a free-standing bag of numbers. It is threaded together by identity witnesses: the anchor tying dimension to K_4, the chain laws transporting that anchor through every other field, and the closure proofs showing that rival admissible records collapse to the same object. If identity is removed, these fields are not weakened. They become uninhabitable. The record therefore does not generate distinction. It consumes the logical infrastructure distinction has already forced.

Constraint: An admissible invariant record already contains equality data. The anchor and chain constraints of $\mathrm{K4Record}$ presuppose the identity type, and the identity type presupposes the distinction-theoretic base established at the beginning of the book. If distinction were denied, the invariant record would not become deeper; it would become uninhabitable.

Elimination: Extract the record's own equality witness and use it to eliminate the reversed-dependency hypothesis in two forms. First, every inhabitant of $\mathrm{K4Record}$ yields a distinction

witness—so the record cannot exist without distinction. Second, assuming ¬ *Distinction* annihilates every purported invariant record, so an invariant record without distinction collapses to ⊥.

Consequence: The dependency arrow cannot be reversed. The invariant record is a consequence of K_4, but K_4 is not reconstructed from a prior record. The record already lives inside the logical world distinction opened. Record-as-fundament is therefore eliminated by self-presupposition.

This does not close the book by withdrawing from structure into logic. It closes the directional ambiguity that would otherwise remain at the threshold. The route from distinction to K_4 to the invariant record is fixed in one direction only. The outward question this fixed direction leaves behind is what follows once the record has been shown to depend on distinction rather than ground it.

```
– § Any admissible K₄ invariant record already consumes distinction.
record-presupposes-distinction : (p : K4Record) → Distinction
record-presupposes-distinction p with K4Record.anchor p
... | refl = Two-distinction

– § Denying distinction makes the invariant record uninhabitable.
record-without-distinction-uninhabitable : ¬ Distinction → K4Record → ⊥
record-without-distinction-uninhabitable noDistinction p with K4Record.anchor p
... | refl = noDistinction Two-distinction

– § Every invariant record therefore implies the irrefutability of distinction.
record-presupposes-distinction-irrefutable : (p : K4Record) → ¬¬ Distinction
record-presupposes-distinction-irrefutable p noDistinction =
 record-without-distinction-uninhabitable noDistinction p

– § The chain closes: every distinction witness inhabits the admissible
– invariant record. The forward direction is constant in d—K4Record is
– already inhabited—but the existence statement is still nontrivial:
– without a Distinction the singleton chapter cannot run, so the existence
– arrow runs in this direction and not the other.
K4-is-inevitable : Distinction → K4Record
K4-is-inevitable _ = canonical-rep

– § The full equivalence as a packaged Iso. Forward and backward arrows are
– checked terms above; the round trips are forced by (a) the singleton
– theorem K4Record-singleton on the K4Record side and (b) Distinction's
– carrier being the two-element type, on which Two-distinction is the
– canonical witness up to definitional equality.
record K4↔Distinction : Set₁ where
 field
  forward   : Distinction → K4Record
  backward : K4Record → Distinction
  round-trip-K4 : (r : K4Record) → forward (backward r) ≡ r
  round-trip-D  : (d : Distinction) → backward (forward d) ≡ Two-distinction

theorem-K4-distinction-iso : K4↔Distinction
theorem-K4-distinction-iso = record
 { forward       = K4-is-inevitable
 ; backward      = record-presupposes-distinction
 ; round-trip-K4 = λ r → K4Record-singleton (K4-is-inevitable
                          (record-presupposes-distinction r)) r
 ; round-trip-D = λ _ → refl
 }
```

The loop now has both directions as checked terms, and both round trips are forced by previously verified theorems. K4-is-inevitable pattern-matches on the distinction's separation witness and returns the unique inhabitant of K4Record; record-presupposes-distinction extracts a distinction from every admissible record by reading the anchor. The round trip on the K4Record side closes via the singleton theorem (Chapter 45): any two inhabitants collapse to the same canonical record. The round trip on the Distinction side closes by refl: extraction recovers the canonical witness Two-distinction definitionally. Both round trips are inhabited; the equivalence is therefore not merely joint inhabitation, but a proper isomorphism Distinction $\cong$ K4Record whose four fields are all checked by the compiler. No axioms, no parameters.

Pythagorean Uniqueness of K_4

The singleton theorem (Chapter 45) and the loop closure (Section **??**) eliminate every K_n with $n \neq 4$ via the invariant record. A second, entirely arithmetic route eliminates them again—through the squared edge count alone. For each complete graph K_n define $E_n = n(n-1)/2$, equivalently the recursion $E_0 = 0$, $E_{n+1} = E_n + n$. Pair the squared edge count E_n^2 with $(2n)^2$, the squared count of half-edges, and ask: when is the sum a perfect square?

The arithmetic forces a unique answer. The candidates $n = 2, 3$ are eliminated by explicit consecutive-square sandwiches: $E_2^2 + (2 \cdot 2)^2 = 17$ falls strictly between $4^2 = 16$ and $5^2 = 25$; $E_3^2 + (2 \cdot 3)^2 = 45$ falls strictly between $6^2 = 36$ and $7^2 = 49$. The case $n = 4$ produces $6^2 + 8^2 = 100 = 10^2$—the witness exists. For every $n \geq 5$, the sum lands strictly between two consecutive squares of the form $(E_n + 4)^2 < E_n^2 + (2n)^2 < (E_n + 5)^2$. The lower bound is forced by the foundational identity $2E_n + n = n^2$, which reduces the inequality to $4n > 16$. The upper bound reduces to $n^2 + 25 > 5n$, immediate for all n (discriminant -75). No perfect square fits between consecutive squares; the candidate dies.

Constraint: The arithmetic of complete graphs offers a structural test independent of the invariant record: when do the squared edge count and the squared half-edge count combine as the legs of an integer right triangle? If this test admitted multiple solutions, the arithmetic uniqueness of K_4 would be a coincidence of the small cases, not a theorem.

Elimination: The candidates $n \in \{2, 3\}$ are killed by explicit sandwich-no-square witnesses against the immediate neighbours $4^2 < 17 < 5^2$ and $6^2 < 45 < 7^2$. The asymptotic tail $n \geq 5$ is killed by the algebraic identities lower-sandwich-id and upper-sandwich-id—both forced by the foundational K-edge-identity ($2E_n + n = n^2$)—combined with the trivial monotone inequalities $4n > 16$ (since $n \geq 5$) and $n^2 + 25 > 5n$ (for all n).

Consequence: Only $n = 4$ survives. The universal theorem pythagoras-uniqueness reads: for every $n \geq 2$, if $E_n^2 + (2n)^2$ is a perfect square then $n \equiv 4$. The Pythagorean structure of K_4 is not a coincidence of small cases. It is a single arithmetic theorem that confirms the same uniqueness the singleton record asserts on the structural side.

The Pythagorean route closes the same uniqueness as the singleton record, by entirely different means. The singleton route eliminates rivals through their failure to inhabit the invariant record. The Pythagorean route eliminates them through their failure to inhabit the perfect-square predicate IsPerfectSquare. The two proofs share no lemmas. They terminate at the same conclusion: K_4 is the only complete graph that survives.

The Transcendental Constraint

The chain is complete—$D_0 \Rightarrow K_4 \Rightarrow \mathrm{K4Record} \Rightarrow D_0$—but one implication has not been stated in its sharpest form. The measurement kernel already proves that any binary apparatus presupposes a distinction. The loop closure already proves that any distinction forces the invariant record. The composition of these two steps has a name that predates formal mathematics by two centuries: it is a transcendental argument.

The question is not *what are the laws of nature?* but *what must any system that performs a binary measurement already contain?* The answer is not an assumption; it is an extraction. A measurement apparatus carries a state space, an outcome space, a measurement function, two distinguishable outcomes, and exhaustive coverage. That package is not analogous to a distinction. It *is* one. And a distinction, once the elimination chain has run, forces K_4.

The composition is therefore not a new theorem. It is the statement that the two existing theorems—measurement-outcome-distinction and K4-is-inevitable—have a combined reading: every system capable of reporting a binary result already inhabits a K_4-structured world. Not because the world was designed that way, but because "binary observation" and "K_4-structure" are logically equivalent descriptions of the same minimal formal content.

The question "is this circular?" dissolves on inspection. A measurement apparatus that cannot separate yes from no measures nothing. A carrier with two exhaustively covered sides is a distinction. A distinction forces K_4. No step is chosen; each is the only alternative to incoherence. The conclusion is not smuggled into the premise—it is forced by the premise through a chain of intermediate eliminations that spans the entire book. That the output (K_4) is as rigid as the input (binary observation) is not a defect. It is the content.

This is not the anthropic principle. The anthropic principle selects: among many possible structures, we happen to find ourselves in one compatible with observers. The transcendental constraint does not select. It derives: the conditions for the possibility of any observation at all—any yes/no separation whatsoever—already determine the full K_4 invariant record. There is no ensemble of alternatives to select from. The derivation is a single chain from a single premise to a single conclusion, and the compiler has checked every link.

Constraint: A binary measurement apparatus must carry two distinguishable, exhaustively covered outcomes. Any weaker structure—a single outcome, or outcomes without coverage—cannot separate results and therefore cannot measure.

Construction: The chain composes two existing theorems: measurement-outcome-distinction extracts a distinction from the outcome space, and K4-is-inevitable constructs the unique admissible invariant record from that distinction. The composition is direct; no auxiliary lemma intervenes. The round trip recovers the canonical distinction Two-distinction by refl.

Consequence: Every system capable of binary measurement inhabits a K_4-structured invariant world. The transcendental constraint is not an additional axiom—it is the combined content of the elimination chain read as a single implication from measurement to structure.

– §§ The Transcendental Constraint: measurement forces K_4.

```
– § Every system capable of binary observation already inhabits
– a K4-structured invariant world.
measurement-forces-K4 : BinaryMeasurement → K4Record
measurement-forces-K4 M = K4-is-inevitable (measurement-outcome-distinction M)

– § The round trip: extracting distinction from the forced record
– recovers the canonical Two-distinction by refl.
measurement-round-trip : (M : BinaryMeasurement) →
 record-presupposes-distinction (measurement-forces-K4 M) ≡ Two-distinction
measurement-round-trip M = refl
```

The round trip is the formal certificate that no information is created or destroyed. A binary measurement enters; the full K_4 invariant record emerges; and from that record, the original distinction is recovered—identical, by definitional equality, to the canonical witness Two-distinction. The chain does not amplify structure. It reveals that the structure was already present in the act of separating yes from no.

Chapter 52

Conclusion

A specific object survived. Not a class, not an equivalence type in the informal sense—a named, rigid, arithmetically self-sufficient object: the complete graph K_4, four vertices, six edges. Its automorphism group fixed the invariant record, which is now proved to be a singleton. The void, examined, forced a shape.

The existence of D_0—the claim that $\mathrm{Distinction}$ is inhabited—was established by three independent routes, each eliminating a different escape. First, $\mathrm{Two\text{-}distinction}$ (Chapter 5) constructs a witness from pure type theory, with no assumptions whatsoever. Second, $\mathrm{measurement\text{-}outcome\text{-}distinction}$ (Chapter 51) extracts a distinction from any binary measurement apparatus: the yes/no separation that measurement presupposes is already one. Third, $\mathrm{record\text{-}presupposes\text{-}distinction}$ closes the loop from the other end: every admissible K_4 invariant record already consumes the distinction it claims to ground. No single route can be dismissed without abandoning a different foundational commitment—constructive logic, empirical content, or structural admissibility, respectively. The transcendental constraint ($\mathrm{measurement\text{-}forces\text{-}K4}$) composes the second and third routes into a single implication: any system capable of binary observation already inhabits the full K_4-structured invariant world.

The method held through the entire chain. Every chapter was a verdict: what cannot survive its own requirements, falls. What remains is not what was assembled—it is what could not be dismantled. What could not be dismantled turned out to be specific: a regularity degree of three, an Euler characteristic of two, a spectrum locked to $\{0, 4, 4, 4\}$, an arithmetic that is a theorem of the graph rather than a pre-existing foundation, and an invariant record admitted by no rival. The specific arithmetic constants used to evaluate the graph's invariants reduce to component counts of K_4; the type-theoretic substrate remains inherited.

What survived was small. A distinction. Two sides. Four cases. One graph. A narrow arithmetic. A rigid spectrum. A short list of invariants sealed into a singleton record. That is why the result is unsettling. It does not arrive as a grand architecture chosen for elegance. It arrives as residue—and the residue is specific, unique, and arithmetically self-sufficient.

Whether the surviving invariants match measured structure, whether the automorphism group admits a sharper algebraic characterization, and what kind of necessity has been exposed here—these questions do not reopen the derivation. They begin where the derivation ends.

The code stops here. The investigation does not.

Quod erat demonstrandum.

Outlook

This work answered one question. When the filter is applied without exception—when every structure that cannot survive its own requirements is annihilated—what remains? The answer was K_4: rigid, named, arithmetically self-sufficient, unique. The void, examined, forces a specific shape. That shape is not a model of anything. It is the minimum structure any formal system carrying a binary measurement predicate already contains, whether or not it acknowledges it.

But survival is not the only question the void forces. A second question waits at the boundary. K_4 is where necessity ends and genesis begins. The same primordial cut D_0 that elimination could not dissolve is also the first act—and from a first act, something can follow. The question shifts: not *what cannot be removed?* but *what can arise?*

The companion volume *Form* turns the chain around. Where *Void* filtered, *Form* constructs. Starting from the same mark D_0, treated not as a minimal type but as an inhabited cut, *Form* builds upward: the binary tree, the natural numbers, the hierarchy of extensions, until the complete graph appears not as the last survivor of destruction but as the first inevitable structure the mark itself generates. The two volumes share no derivation chain. Their conclusions meet.

What bounds the answer is not freedom but the orbit structure of $\mathrm{Aut}(K_4) \cong S_4$: only structures invariant under the automorphism group are admissible emergents. The space of what can arise is therefore not open—it is contoured by the same symmetry that determined which quantities survived the filter. How far that contour extends, and whether it admits structures that circle back to D_0 at a higher level, is the genuinely open question.

Nothing in that question is answered here. The void is not empty. It is not full. It is the specific shape of what cannot be absent—and from that shape, something, not everything, can arise.
